Edited by Carol A. Barnes, University of Arizona, Tucson, AZ, and approved March 25, 2019 (received for review February 4, 2019)

Spatial navigation is emerging as a critical factor in identifying preclinical Alzheimer’s disease (AD). However, the impact of interindividual navigation ability and demographic risk factors (e.g., APOE, age, and sex) on spatial navigation make it difficult to identify persons “at high risk” of AD in the preclinical stages. In the current study, we use spatial navigation big data (n = 27,108) from the Sea Hero Quest (SHQ) game to overcome these challenges by investigating whether big data can be used to benchmark a highly phenotyped healthy aging laboratory cohort into high- vs. low-risk persons based on their genetic (APOE) and demographic (sex, age, and educational attainment) risk factors. Our results replicate previous findings in APOE e4 carriers, indicative of grid cell coding errors in the entorhinal cortex, the initial brain region affected by AD pathophysiology. We also show that although baseline navigation ability differs between men and women, sex does not interact with the APOE genotype to influence the manifestation of AD-related spatial disturbance. Most importantly, we demonstrate that such high-risk preclinical cases can be reliably distinguished from low-risk participants using big-data spatial navigation benchmarks. By contrast, participants were indistinguishable on neuropsychological episodic memory tests. Taken together, we present evidence to suggest that, in the future, SHQ normative benchmark data can be used to more accurately classify spatial impairments in at-high-risk of AD healthy participants at a more individual level, therefore providing the steppingstone for individualized diagnostics and outcome measures of cognitive symptoms in preclinical AD.

Alzheimer’s disease | spatial navigation | personalized health care | APOE genotype | preclinical diagnosis

Spatial navigation is a promising cognitive fingerprint for understanding Alzheimer’s disease (AD) pathophysiology (1–8) and has been adopted by many high-profile clinical trials (such as the European Prevention of Alzheimer’s Dementia Consortium) to improve the sensitivity of neurocognitive testing and assess the efficacy of potentially disease-modifying treatments. In fact, brain areas affected by AD pathophysiology in the preclinical stage (including the entorhinal cortex, posterior cingulate cortex, and precuneus) form the key nodes in the spatial navigation pathway (6, 9–13). Recent evidence suggests that abnormal spatial navigation patterns may be present before episodic memory deficits, which are the current gold standard for AD diagnosis (6, 14, 15).

A major challenge at this stage, however, is to understand how interindividual and demographic factors affect spatial navigation to identify earliest pathological spatial navigation changes in AD (16–19). Understanding diversifying factors that influence variability in spatial ability in the healthy population and individuals at risk to develop AD will advance the diagnostic power of the spatial tests and support more personalized diagnostic and treatment approaches (17, 20–23). Among factors underlying navigation, age is a well-documented predictor of declining spatial abilities, as older adults show a strong bias toward egocentric rather than allocentric strategies (24, 25) leading to suboptimal navigation performance (26). Age-related decline in allocentric process are due to changes

Significance

We report that assessment of navigational behavior using the Sea Hero Quest app provides a means of discriminating healthy aging from genetically at-risk individuals of Alzheimer’s disease (AD). It further highlights that the global Sea Hero Quest database can be employed as a normative benchmark dataset to efficiently determine the significance of spatial abnormality suspected to be indicative of incipient AD on an individual level.

entorhinal cortex of apoE4 carriers are functionally unstable, leading to a boundary-driven error correction during wayfinding (49).

Taken together, there is increasing evidence that spatial deficits, in particular related to wayfinding, are present in preclinical AD long before episodic memory symptoms emerge. However, at this stage, it is very difficult to employ such knowledge on a clinical level, due to unknown interindividual variability in navigation behavior across persons, which is vital for sensitive and specific diagnostics on an individual level. In the current study, we address this issue by using big data (n = 27,108) for navigation behavior from the Sea Hero Quest (SHQ) app (41, 50) (i) to determine whether we can replicate previous wayfinding effects in APOE ε3ε4 carriers compared with the big data; (ii) to further disentangle interindividual effects of genetic risk for AD from the effects of sex, age, and baseline cognition on spatial discrepancies; and (iii) to explore whether AD-specific spatial navigation changes can be detected on an individual level, when using big data as a benchmark comparison.

To further examine the different routes taken by the two genetic groups, we plotted the exact trajectory of each participant on wayfinding levels 6, 8, and 11 using (x, y) coordinates generated during game play and found that ε3ε4 carriers show a lower average distance to border than their ε3ε3 counterparts (Fig. 2D–F). On levels 6 and 8, ε3ε4 carriers deviate from the shortest distance between the checkpoints and travel toward the border of the environment compared with the ε3ε3 carriers, who tend to navigate along the center of the virtual environment. To check whether the increase in wayfinding distance in ε3ε4 carriers compared with the ε3ε3 group was driven by any specific level, fixed-effects linear models were fitted for levels 6, 8, and 11 to test whether the properties in one specific level captured this effect, or whether this effect was an accumulative error over the three wayfinding levels. Using the same exploratory variables as in the final base model, the ε4 allele was found to increase wayfinding distance on level 6 [F(ε4) = 5.48, P = 0.023] and level 8 [F(ε4) = 4.08, P = 0.04], but not on level 11 (SI Appendix, Fig. S2; also see SI Appendix, Fig. S5 for diagnostic plots underlying key assumptions of the linear mixed models).

Genotype and Sex Effect on Wayfinding. No effects of sex were found on wayfinding distance as men (M = 4.06, SD = 0.87) and women (M = 4.22, SD = 0.91; b = 0.02, P = 0.12) took similarly efficient paths, but sex did affect duration taken to complete wayfinding levels, with men (M = 4.33, SD = 1.09) requiring less time to complete levels than women (M = 5.26, SD = 2.17; b = 0.39, P = 0.02; SI Appendix, Fig. S3A). Importantly, no interactive effects of genotype and sex on wayfinding distance or wayfinding duration were uncovered.

Genotype and Sex Effects on Path Integration. We then tested the effects of genotype and sex levels on flare accuracy, a measure of path integration. No main effect of genotype (b = 0.04, P = 0.14; Fig. 2C) and no genotype by sex interactions were found. However, sex had a significant main effect on flare accuracy, with men (M = 5.11, SD = 1.3) scoring higher than women (M = 4.31, SD = 1.4; b = −0.36, P = 0.04; SI Appendix, Fig. S3B).

Memory and Spatial Navigation as Predictors of APOE Genotype. The sensitivity and specificity of a traditional memory task to predict APOE genotype was compared with spatial navigation on SHQ was done using logistic regression and receiver operating characteristic (ROC) curves. This was motivated by the prediction that memory deficits would not be detectable on current gold standard episodic memory tasks. Covarying for sex, nonverbal episodic memory (3-min total recall score for the ROCI) and wayfinding distance in SHQ were used as separate predictors in two logistic regression analyses. The regression model for wayfinding

Data are mean (SD).
Having determined the diagnostic utility of SHQ for APOE genotyped compared with standard memory test, we wanted to examine the utility of the population-level benchmark dataset as a normative control sample that could be used by clinicians in diagnostic settings. We took advantage of the fact that the benchmark population, we plotted each of the normal distribution of the UK population—predominantly includes e3e3 carriers (75%) and performed a ROC curve with the e3e4 and the benchmark data as a representative of the population—showing both navigation and delayed recall as predictors of APOE genotype (Fig. 3). Consistent with the above, area under the curve (AUC) values indicated that wayfinding distance (AUC, 0.714; SE, 0.068; 95% CI, 0.555–0.822; pink curve), but not delayed recall (AUC, 0.541; SE, 0.074; 95% CI, 0.286–0.578; gold curve), has a significant level of diagnostic accuracy.

Discussion

Our results show that (i) we can replicate previous wayfinding changes in APOE4 gene carriers; (ii) sex differences significantly impact on wayfinding behavior, but the effect of sex is negligible compared with APOE genetic risk; (iii) healthy “at-genetic-risk” of AD with no memory deficits can be distinguished on wayfinding measures on an individual level.

In more detail, using navigation benchmark big data and smaller APOE genotyped cohorts, we show that adults at genetic risk of AD with no clinically detectable cognitive deficits, not only navigate further during wayfinding, but show a bias in navigating toward the border of the virtual SHQ environment in large open areas. This supports the hypothesis that suboptimal navigation performance is present in preclinical AD and that this is detectable on levels of the SHQ game, even when a closely matched demographic sample is provided by the global SHQ dataset. We also show that while sex accounts for variation in navigation performance, sex does not reduce the sensitivity of SHQ to discriminate healthy aging from genetically at-risk individuals of AD.

Although adults at genetic risk of AD deviate from the shortest route (often the Euclidean between the checkpoints) toward the environmental border of the SHQ environment, they successfully completed the wayfinding levels albeit suboptimally. Thus, we hypothesize that the navigational deficits detected here reflect an error corrective strategy (49) for which environmental boundaries hold valuable navigational cues that aid the navigators’ ability to self-localize and find their way through the environment when navigational uncertainty ensues. The neural substrates that give rise to the navigational uncertainty in the genetically at-risk group is most likely induced by errors in the grid cell system within the entorhinal cortex (see SI Appendix for further discussion). The entorhinal cortex is not only one of the first sites of AD pathology in the brain (13) but is also crucial for facilitating shortcut wayfinding behaviors and optimal navigation behavior (51). Given that grid cells compute large-scale information (30, 31) and encode representations of self-location by measuring distance traveled by the navigator (32, 33), it is not surprising grid cell dysfunction results in navigational discrepancies in at-risk individuals of AD.

Given that phenotypic heterogeneity currently reduces the diagnostic and prognostic power of neurocognitive evaluations for early AD, we also sought to investigate whether demographic and neuropsychology diversity impact navigation. The effect of the genotype that was most prominent when the environmental space was large and open (level 6 and 8). In terms of sex, we did find strong evidence of better performance in males on baseline navigation ability but no evidence to suggest that males at genetic risk were less vulnerable (in the preclinical stage at least) to the.
effect of the APOE e4 genotype than women at genetic risk. In our opinion, this is a critical finding as it suggests that sex difference may not act on the phenotypic presentation of navigation deficits in the early asymptomatic stage of the disease. A recent metaanalysis (52) reports that women are particularly vulnerable to early underlying pathology between the ages of 55 and 70. Thus, whether sex and genotype interact to predict navigational ability on SHQ in later preclinical or prodromal stages of AD remains to be investigated. In the interest of diagnostic sensitivity, the time at which an increased female susceptibility to underlying pathology manifests behaviorally is a high priority. Although we found a sex-independent navigational deficit in adults at genetic risk of AD, evidence for strong spatial disparities on navigation performance across the sexes globally (41) suggest that it is indeed appropriate to consider the need to stratify risk assessment by sex. For example, when genotype status is unknown, considering sex difference may hold prognostic value as many high-profile previous studies already suggest (17, 21, 35).

Based on data presented here on a population level and elsewhere, we now know that demographic diversity based on age, sex, and nationality act on navigation proficiency, and men perform better at digital and real-life spatial navigation tasks (53). This finding, coupled with a plethora of preexisting evidence for natural age-related decline in spatial navigation (26), means that we must establish personalized normative measures to accurately assess spatial disturbances that have not been well-established as a underlying feature in preclinical AD pathology. From a clinical standpoint, clinicians and researchers should be advised to consider not only age but also the sex of their putative patient before inferring pathological related spatial impairment. From a research perspective, researchers should work toward providing demographically corrected benchmarked scores for standardized neuropsychological test. To date, obtaining normative data of this nature has been challenged by heterogeneity in methodological approaches used to measure spatial navigation and uncertainty about population-level differences in cognitive performance. Consistency across our nonrisk control group and the benchmark scores is compelling evidence that SHQ may provide unique benchmarking data, on a global scale, by controlling for the demographical factors such as sex, advanced age, and cultural background, factors that will alter how individuals perform on SHQ (41). Although level of education was included
to refine the population data, education did not have a compelling effect on navigation performance in the global SHQ database. Further research is required to determine what demographic factors beyond age, sex, and nationality will increase the sensitivity and specificity of navigation test for underlying preclinical AD.

Despite illustrating the clinical utility of epidemiological data gathered on a global scale using the SHQ game, our study has several limitations. First, we focus on preclinical rather than symptomatic AD, seeking to evaluate the prognostic value of SHQ rather than validate SHQ data as a potential diagnostic tool. However, given that many excellent cognitive diagnostics measures exist for symptomatic AD, we question whether navigation measures have true utility in this aspect. Instead, identification of subtle cognitive preclinical changes will be of greater future importance to complement other biomarkers as diagnostic and treatment outcome measures. Second, only 47% of all e3/e4 carriers develop symptomatic AD. This is consistent with about 50% of the e3/e4 individuals in this study being impaired relative to the demographically corrected benchmark. Longitudinal studies are needed to truly determine how predictive spatial navigation combined with genotypic information is in the preclinical stages of the disease however. Further replication of our findings with preclinical cohorts defined by multiple cognitive, genetic, and neurological markers is desirable, although it is promising that we replicate previous boundary findings (7). Moreover, although education was considered in the individualized approach to diagnosis of “at-risk” AD, ~40% of the genotyped cohort has 15+ y of education and 50% of the cohort working in “professional” fields vs. skilled or low-skilled/manual, potentially leading to an over-representation at the educated individuals in this genotyped sample. Last, although best efforts were made to control for gaming proficiency, we cannot completely rule out a potential influence of previous gaming experience contributing to the observed male advantage in the data. Still, considering that we are investigating a 50- to 75-y-old cohort, gaming proficiency should not play such a large role. More importantly, the difference of male and females in the SHQ data across ages does not change, suggesting that gaming proficiency plays only overall a minor role in assessing spatial navigation via an online app.

In conclusion, our work supports the hypothesis that navigational discrepancies are present in preclinical AD and can be captured by SHQ. We show promising evidence that normative data generated from the 3.7 million people who played SHQ worldwide may in the future help us to create a prognostic test based on navigational proficiency—to help us to understand how the very earliest symptoms of AD is in isolation of potentially confounding demographic factors such as sex, advancing age, educational attainment, or cultural background. This should reduce the problematic nature of phenotype variation obscuring the assessment of spatial disorientation as a first symptom of AD and offer the promise of individually tailored solutions in healthcare settings. Thus, spatial navigation emerges as a promising cognitive fingerprint, which can complement existing biomarkers for future AD diagnostics and disease intervention outcome measures.

**Materials and Methods**

**Participants.**

APOE genotyped cohort. Between February 2017 and June 2017, 150 people between 50 and 75 y of age were recruited to participate in a research study at the University of East Anglia. All 150 participants were prescreened for a history of psychiatric or neurological disease, history of substance dependence disorder, or any significant relevant comorbidity. All participants had normal or corrected-to-normal vision. Family history of AD and history of antidepressant treatment with serotonin reuptake inhibitor drugs was retrospectively obtained. Saliva samples were collected from those who passed this screening, and apoE genotype status was determined.

In total, 69 participants underwent cognitive testing. As just 23% of the population carry APOE e3/e4, all participants in our sample who tested positive for the e3/e4 allele completed cognitive testing. We selected a subset of the e3/e4 carriers that form the majority of the population (75%) to match the e3/e4 risk group for age and sex (see SI Appendix, Table S1, for group background characteristics). We did not include a third genetic subgroup of homoygous APOE e4 carriers from the tested cohort, because they were too rare (n = 5), although their scores are reported in SI Appendix. E2 carriers were also excluded. During testing, three participants showed signs of distress, and their data were excluded from subsequent analyses. One participant scored lower than 86 on the Addenbrooke’s Cognitive Examination and was classified as mildly cognitively impaired and excluded from the study. The final group sizes (postexclusion) were as follows: apoE e3/e3, n = 29, and apoE e3/e4, n = 31. Written consent was obtained from all participants, and ethical approval was obtained from Faculty of Medicine and Health Sciences Ethics Committee at the University of East Anglia (reference FMH/2016/2017-11).

**The benchmark population.** A unique population-level benchmark dataset was generated by extracting a subset of the global SHQ database (41) that matched the SHQ wayfinding APOE 0.04 0.03 0.07 0.77

Before the main analysis, competing mixed-effect models were tested to examine the best model fit and model simplification based on standard Akaike information criterion and Bayesian information criterion. The final model in the table above (featuring subject-level random effects) was adopted since it demonstrated the best model fit for the data and was retained for the main analysis. Higher values on wayfinding distance and wayfinding duration indicate poorer performance; conversely, higher values on flare accuracy indicate better performance. *P < 0.05.
the demographic profile of our laboratory-based genotype cohort, namely players from the United Kingdom aged 50–75 y old. Following extraction, 14,470 British men and 12,710 British women (n = 27,180) remained as a representative normative sample of healthy navigation performance on the basis that epidemiological studies have shown that the majority of the general population (~75%) are non-apoE4 carriers (36). Participants from the benchmark sample were given the option to opt in or opt out of the data collection when they played the game on their personal mobile phone, iPad, or tablet. If a participants’ response was to opt in, their SHQ data were anonymized and stored securely by the T-Systems’ data center under the regulation of German data security law. Ethical approval was previously granted by Ethics Research Committee CPB/2013/015. For more information on the global SHQ database, see www.seaheroquest.com/site.

Outcome Measure. The SHQ app was developed in 2015 by our team and funded by Deutsche Telekom. The programming of the game was conducted by Glitchers Ltd. The SHQ benchmark analysis was funded by Alzheimer’s Research UK. The app was created to be a reliable and valid measure of spatial navigation performance both in monitored research settings and unmonitored at-home settings (41, 53). It was made available for free on the App Store and Play Store from May 2016, and since then over 4 million people have downloaded the app worldwide. The game performance is divided into two main domains: goal-oriented wayfinding and path integration.

Goal-oriented wayfinding. In wayfinding levels, players initially see a map featuring a start location and several checkpoints to find in a set order, as illustrated in Fig. 1. Checkpoints are buoys with flags marking the checkpoint number. Participants study a map of the level for a recorded number of seconds. When participants exit the map view, they are asked to immediately find the checkpoints (or goals) in the order indicated on the map under timed conditions. As participants navigate the boat through the level, they must keep track of their location using self-motion and environmental landscape cues such as water-land separation. The initiation time is zero as the boat accelerates immediately after the map disappears. If the participant takes more than a set time, an arrow appears pointing in the direction along the Euclidean line to the goal to aid navigation. To familiarize themselves with the virtual environment and game controls, participants started with two easy learning levels 1 and 2. Wayfinding levels generate two measures of interest as follows:

i) “Wayfinding distance” traveled to visit all required checkpoints is defined as the wayfinding distance between all points recorded and is a proxy for navigation efficiency. To navigate efficiently, individuals need to form and retain a cognitive map of the environment (after viewing the map at the start of the level) and then consistently update self-location in that cognitive map based on the visual cues from the SHQ game.

ii) “Wayfinding duration” is defined as the time in seconds to complete a wayfinding level. While inefficient navigation also results in longer time to visit all checkpoints, increased duration is primarily due to the amount of acceleration that the player used. By “swiping up,” one can increase the speed of the boat temporarily, therefore reducing travel time but not changing the distance traveled at all. Since speeding up requires confidence in one’s sense of direction, we take the resulting wayfinding duration score as less representative of participants’ ability to navigate along the shortest path and more representative of nonnavigational factors such as confidence or the tendency to sample more cues before speeding up.

Flare accuracy. In path integration levels (in the game, this is measured by flare accuracy on levels 9 and 14), participants are not provided with an allocentric map. Instead, they immediately navigated along a river to find a flare gun. Once they find the flare gun at the end of the river, the boat rotates by 180°, and participants are asked to choose one of three possible directions (right, front, left) that they believe points to the starting point. This level requires participants to (i) form an accurate representation of the starting point relative to their position and (ii) integrate this representation with a representation of the direction they are facing after the rotation [see Tu et al. (15) for a similar path integration-based experimental design]. In this case, gaming proficiency was not advantageous because participants simply view navigate a single passage and are then required to choose the A, B, C direction as a single response. Depending on their accuracy, players receive one, two, or three stars.

Procedure. Data collection. Spatial navigation data were collected for both the APOE genotyped cohort and benchmark datasets using SHQ, a digital game that we predesigned to measure human navigation ability. Decisions on level selection was made by considering which levels had the most normative data and level type/difficulty (wayfinding or path integration). Levels 1 and 2 were included for learning and practice navigating the boat, as well as normalizing the data for app interaction with player proficiency. Levels 3–5 were excluded as they

Fig. 4. Each ±2σ carrier score (red line) on SHQ distance plotted against the normal distribution of scores from an age/sex/education-matched subpopulation of the benchmark dataset (green histogram). Wayfinding distance scores are on the x axis and frequency of the benchmark population on the y axis. Sex is represented as male (M) and female (F). Age is illustrated under each distribution right of sex.
did not challenge participants’ navigation skills and were intended to ease the players into the game. Furthermore, starting with level 14, the sample size of the benchmark population drops substantially. This then left us with three wayfinding levels (6, 8, and 11) and two path integration levels (9 and 14). Participants in the laboratory-based APOE cohorts provided their demographic information regarding their sex, age, location, and educational attainment (high school, college, university) demographics in-app before playing SHQ. APOE genotyping DNA was collected using a Darcon tpq buccal swab (Le11SRG; Fisher Scientific). Buccal swabs were refrigerated at 2–4 °C until DNA was extracted using the QIAGEN QIAamp DNA Mini Kit (M15 6SH; QIAGEN). DNA was quantified by analyzing 2-μL aliquots of each extraction on a QUBIT 3.0 fluorometer (LE11 SRG; Fisher Scientific). Successful DNA extractions were confirmed by the presence of a DNA concentration of 1.5 μg or higher per 100 μg of AE buffer as indicated on the QUBIT reading. PCR amplification and plate read analysis was performed using Applied Biosystems 7500 Fast Real-Time PCR System (TNZ2 4FD; Thermo Fisher Scientific). TaqMan Genotyping Master Mix was mixed with two single-nucleotide polymorphisms of APOE (rs429358 at codon 112 and rs7412 at codon 158). These two single-nucleotide polymorphisms determine the genotype of APOE2, E3, and E4 (2007; Applied Biosystems).

Statistical Analysis. The data were analyzed using SPSS (version 23), RStudio (version 1.0.153), and MATLAB (R2017a). χ² and simple two-tailed t tests were used to test the significance of any demographic or neuropsychological differences between the genetic groups in our laboratory cohort. When quantifying the group differences, Cohen’s d was used as a measure of effect size. To control for the influence of player proficiency on device, the SHQ data were preprocessed in MATLAB and participant performance on each level within the game was divided by the sum of the two practice levels:

\[
\text{Level } \text{N normalized} = \ln \left( \frac{\text{level } N}{\text{level } 1 + \text{level } 2} \right)
\]

To assess the fixed effects of genotype and sex, we first compared competing statistical models with the inclusion and exclusion of different demographic factors using the nlme package in R (https://cran.r-project.org/web/packages/nlme/index.html) that allows fitting fixed and random effects to evaluate the most appropriate model for data. In each model, subject-level random effects were included to vary the intercept for each subject and importantly to account for interdependence between repeated measures from playing multiple levels of the game. Three sets of linear models were fitted that included the following outcome variables: (i) wayfinding distance and (ii) wayfinding duration, using scores from SHQ levels 6, 8, and 11 completed by each subject, and (iii) flare accuracy on each of the two path integration levels (9, 14). Model selection was based on relative goodness of fit and model parsimony (determined using gold standard Akaike information criterion and Bayesian information criterion, respectively).

Age, sex, and genotype were retained as explanatory variables for the final model for each of the outcome variables. ACE defined by total score on the Addenbrooke’s Cognitive Examination III screening tool (54), education, occupation, time spent on viewing the wayfinding maps (see Fig. 1 for maps), and nonverbal episodic memory (defined by 3-min delayed recall on Rey-Osterrieth Complex Figure Test (ROCF) (55)), were tested in the final model but did not exhibit a significant main effect and were excluded to retain the maximum degrees of freedom. Once the best-fit model was identified, standardized residuals were extracted and plotted against fitted values to examine underlying assumption of normal distribution and heteroscedasticity. We also tested for an interaction between genotype and sex. All statistical tests are two-tailed: P < 0.05.

To ensure that the benchmark population reflected the demographic profile of our laboratory-based cohort, we could only use a subpopulation of our own SHQ database. We developed a data extraction method using MATLAB (code, data, associated protocols, and materials available from authors on request) that allowed us to generate the population-level database. These data were then preprocessed using the same normalization procedure as detailed above. Linear mixed models examined the effects of sex and age on a population-level benchmark. Finally, logistic regression was used to quantify how well SHQ variables such as distance traveled could classify APOE risk status using both the laboratory-based sample and the benchmark population. ROC curves were used as measures of sensitivity and specificity of SHQ as opposed to standard memory tasks such as the ROCF test to detect preclinical AD.
