59 **Introduction**

60 Open ocean waters store (sequester) carbon out of contact with the atmosphere on decadal to
61 millennial timescales, exerting a major control on global climate by regulating atmospheric
62 carbon dioxide partial pressure ($p\text{CO}_2$)¹. The magnitude of ocean carbon storage is governed
63 by two well-established mechanisms that maintain a surface-to-deep ocean gradient of
64 dissolved inorganic carbon (DIC) – the biological and the solubility pumps^{2,3}. The solubility
65 pump delivers cold, dense, DIC-rich waters to depth mostly at high latitudes, whereas the
66 biological pump globally exports particulate organic carbon (POC) from surface waters. POC
67 export is largely attributed to the gravitational settling of a subset of the particle assemblage^{1,4}
68 – a process we refer to as the “biological gravitational pump” (BGP).

69 The BGP is the key link between upper ocean photosynthetic carbon fixation, the sustenance
70 of mid-water biota, and carbon storage in the oceans’ interior^{4,5}, and is thought to account for
71 ~90% of the vertical DIC gradient, while the solubility pump explains the remainder¹. In the
72 absence of the BGP, models predict atmospheric $p\text{CO}_2$ would be higher by nearly twofold⁶.
73 Contemporary and paleoceanographic observations both reveal that carbon sequestration by
74 the BGP is affected by environmental changes in light, temperature, stratification and nutrient
75 availability^{7,8}, and can itself drive dramatic climate shifts such as glacial-interglacial cycles⁸.
76 Future climate projections suggest that the functioning of the BGP will be altered by ocean
77 global change^{7,9}, potentially feeding back on anthropogenic climate warming¹⁰. As a
78 consequence, quantification of its functioning requires a reliable baseline of accurate
79 measurements.

80 The underlying principles of the BGP are long established¹¹: organic particles are continually
81 produced and recycled in sunlit surface waters, and a small fraction of these settle into the

82 oceans' interior. The strength of the BGP is often quantified as the rate of particle "export"
83 from the euphotic zone, the surface mixed layer, or across an arbitrary horizon at 100m¹². As
84 they sink, particles undergo myriad transformations, which lead to pronounced vertical
85 attenuation of the particle flux that is often described as a power law relationship, referred to
86 as the "Martin Curve"¹³. The efficiency of the BGP is defined here as the time that exported
87 carbon is kept sequestered from the atmosphere within the ocean's interior. It is driven by the
88 depth scale of flux attenuation and pathways of ocean circulation that carry remineralized
89 carbon dioxide back to the surface¹⁴. Carbon is sequestered for timescales longer than a year
90 by particles that penetrate the permanent pycnocline (beneath the wintertime mixed layer)
91 and up to centuries by those that reach deep water masses (generally >1000m). Together, the
92 strength and efficiency of the BGP determine the total quantity of carbon sequestered
93 biologically in the ocean interior.

94 Recently, analyses of global and regional ocean carbon budgets have identified conspicuous
95 imbalances (i.e., two to three-fold less storage) when BGP export fluxes are compared with
96 those derived from geochemical tracers^{15,16}, highlighting the need to reassess the pathways
97 that contribute to carbon storage. Furthermore, rates of site-specific particle export appear to
98 be insufficient to meet the carbon demand of mid-water life (termed mesopelagic biota) by
99 two-to three-fold¹⁷⁻²⁰, but in one study can be balanced using community respiration¹⁸. There
100 is considerable debate over the reasons for these carbon deficits, ranging from biases inherent
101 in observational technologies^{17,21} to the potential role of other carbon (dissolved and/or
102 particulate) delivery mechanisms to deep waters^{16,22,23}. Traditionally, the biogeochemical
103 functioning of the BGP has been evaluated from quasi one-dimensional (1D) observations of
104 particle flux (Box 1), and extrapolated using Earth System Models (ESMs, parameterised
105 with observations²⁴⁻²⁶) and/or remote-sensing observations²⁶. This approach cannot capture

106 more complex mechanisms of carbon export that are highly variable in space and time (Box
107 1), potentially resulting in the reported carbon budget deficits.

108 Multiple lines of research have revealed the importance of additional export pathways,
109 physically (e.g. subduction) and/or biologically (e.g. large mesopelagic migrators) -mediated,
110 that inject particles to depth, termed here Particle Injection Pumps (PIPs)^{23,27-30}. These
111 mechanisms can potentially export all particle classes to depth, and thus challenge the
112 conventional view of gravitational sinking as the dominant downward pathway for particles
113 into the oceans' interior. The characteristics of PIPs fundamentally change our understanding
114 of biological carbon sequestration: first, PIPs can animate particle transport spatially into
115 three dimensions (3D), in contrast with the BGP where the vertical dimension is predominant
116 (1D); second, global estimates of PIP carbon fluxes are significant relative to those for the
117 BGP^{27,28}, and third, these mechanisms cannot be readily quantified using the traditional
118 toolbox applied to investigate the BGP (Box 1). Overall, the PIPs will increase the strength
119 of the biological pump beyond estimates based on gravitational flux alone, and can change its
120 efficiency by altering the depth of carbon export.

121 The fate of exported carbon following its delivery to depth has also proven more complex
122 and heterogeneous than previously recognized. Particle flux attenuation is now known to vary
123 systematically in space^{14,31,32} and time³³, suggesting the traditional empirical view¹³ must be
124 replaced by a mechanistic one that considers particle composition and architecture, microbial
125 metabolism, and transformation processes¹⁷.

126 Together, these developments stand to reshape our understanding of particle transport and
127 remineralisation in the oceans' interior. Here, for open ocean systems we review: the
128 mechanisms, rates, and depths of particle injection by each PIP; the potential for each
129 mechanism to close observed deficits in ocean carbon budgets; and the corresponding

rem mineralisation depths of exported POC in the deep ocean. We finish by outlining future research directions needed to synthesize these developments into a new mechanistic, four-dimensional (4D) view of carbon export and sequestration. The review does not detail the important role of dissolved organic carbon subduction^{22,23}, nor cover the dark microbial carbon pump³⁴ or chemolithotrophy³⁵ which have been reviewed elsewhere (S-Table 1).

Particle injection pump mechanisms

PIPs differ in their mechanisms, temporal-spatial scales (Fig. 1, Fig. 2a), and/or geographical extent, but have common features: i) they can act on all particles from suspended to sinking (Fig. 1); ii) they typically inject particles below the euphotic zone (i.e., the export depth for the BGP), potentially reaching depths $>1000\text{m}$ ²⁸⁻³⁰ depending on the injection mechanism (Fig. 1, Fig. 2b); iii) they occur concurrently with the BGP but cannot be measured with techniques developed to quantify gravitational settling^{13,32} (Box 1); iv) their dynamic nature (i.e., physical transport^{23,27,28} or patchiness of animal distributions³⁰) means that the interplay between their vertical and horizontal vectors and temporal scales varies significantly (Fig. 1). Hence, a 4D sampling framework is required to constrain them (Box 1). The main characteristics of each PIP are elucidated below.

Particle export driven by physical subduction includes several processes driving the vertical transport of near-surface particles that act on different space/time scales: subduction caused by mixed-layer shallowing (termed the mixed-layer pump^{29,36}); subduction by large-scale (100-1000 km) circulation (termed the large-scale subduction pump)²³; and subduction by mesoscale (10-100 km) to submesoscale (1-10 km) frontal circulation (termed the eddy-subduction pump^{23,27,28}).

Carbon export by the mixed-layer pump is driven by biological accumulation of particles throughout the spring/summer growth season, which are then diluted to the depth of the mixed layer during winter, and left in the oceans' interior during early spring stratification (Box 1). This pump operates on wide-ranging time-scales from days/weeks³⁷ to seasons^{29,37}, predominantly in mid and high latitude regions characterised by strong seasonal variability in mixed-layer depth (Fig. 2a). Although these concepts are long-established³⁶, only recently have they been scrutinised in detail using advances in optical profiling (BGC-Argo) floats and satellite particle proxies to track particle accumulation rates in relation to changes in surface mixed-layer depth (Box 1).

The large-scale subduction pump is a 3D advective mechanism directed from the seasonal mixed-layer into the oceans' interior, driven by Ekman pumping and horizontal circulation across a sloping mixed-layer³⁸. Subduction rates were first estimated for the North Atlantic³⁹, and then globally using data-assimilating models⁴⁰. The wide-ranging subduction rates (1-100 m/year)^{39,40} are small relative to BGP particle settling rates^{11,12}, but subduction occurs over large regions of the global ocean boosting the magnitude of carbon delivery to depth.

The frontal-associated eddy-subduction pump subducts particle-rich surface waters on timescales of days and across spatial scales of 1-10 km, driven by strong vertical circulation associated with fronts and eddies^{27,28,41-44}. Gliders are now used to map 3D dynamic eddying flow fields (Box 1), finding evidence for penetration of high particle stocks (co-located POC and chlorophyll indicative of viable phytoplankton) from the spring bloom, conspicuous as distinct filaments at 100-350 m depth at the eddy periphery²⁸ (Box 1). Mapping revealed the co-location of high POC filaments and negative vorticity to depths near the permanent pycnocline²⁸, and the mechanism is supported by high-resolution simulations in which eddy subduction of particles is a recurring feature⁴⁵⁻⁴⁸. The strength of the eddy-subduction pump

177 is governed by the vigour and penetration of the vertical circulation, in conjunction with local
178 POC stocks over the frontal area^{27,49}. Eddy subduction rates span 1-100 m d⁻¹ (c.f. 20 to >
179 100 m d⁻¹ for the BGP^{11,12}) depending on the eddy or frontal structure. Modelling indicates
180 that these subducted particles are remineralised more rapidly (i.e., at relatively shallow depths)
181 relative to gravitationally-sinking particles²⁷.

182 The concept for the ‘mesopelagic migrant pump’ is based on long-established observations of
183 diurnal vertical migration⁵⁰ (Box 1). This pump extends the remineralisation scale by
184 injecting particles to greater depth before decomposition begins^{51,52}, as determined by gut
185 retention time of migrating animals⁵¹⁻⁵³ and the depth of their migration (typically ~400 m⁵³).
186 The injected particles are zooplankton faecal pellets with sinking rates of 10-100’s m d⁻¹ (ref.
187 51), faster than loosely-packed organic aggregates settling from the surface^{11,12}, and will
188 penetrate deeper in the water column before remineralisation. This pump therefore influences
189 all important facets of the particle flux that govern carbon sequestration – total export rate,
190 depth of peak flux, and flux attenuation depth scale.

191 Diurnal vertical migration results in active subsurface transport and carbon sequestration, and
192 is usually reported for mesozooplankton and often included in BGP estimates⁵¹. However,
193 vertical migration by larger mesopelagic carnivorous organisms (from greater daytime depths
194 than mesozooplankton) are not sampled by conventional BGP approaches^{52,54}. Targeted
195 studies (Box 1) have quantified this pump driven by large mesopelagic migrant carnivores in
196 the Pacific⁵⁴, and other regions (S-Table 1). The underlying mechanism is upward migration
197 to graze mesozooplankton⁵⁴ followed by rapid (hours) downward migration⁵³, with
198 respiration (release of CO₂), exudation, and defecation (release of POC/DOC)^{51,55} often
199 below the permanent pycnocline⁵⁶, at depths up to 600m (Box 1).

Trawl surveys suggest that ~50% of mesopelagic organisms migrate, ranging regionally between 20-90% depending on temperature, turbidity and oxygen concentrations^{54,56}. The carbon sequestration rate by this pathway is governed by the metabolic transfer efficiency of migrators, and particles are injected at their residence depth, often at the upper boundary of oxygen minimum zones where their respiration intensifies oxygen depletion⁵³.

Active transport by vertically-migrating metazoans can also occur on longer timescales (Box 1). For example, in high latitude regions the winter hibernation of copepods (members of the mesozooplankton) at depths between 600-1400m gives rise to a so-called ‘seasonal lipid pump’³⁰: during hibernation, they catabolise carbon-rich lipids accumulated during summer in upper layers and thereby shunt carbon (but not nitrogen and phosphorus) below the permanent pycnocline³⁰. The strength of the seasonal lipid pump is governed by copepod abundance, size and temperature, which together control their respiration rate and help explain the existence of carbon flux hotspots (i.e. patchiness)³⁰.

Another vertical export mechanism that operates on seasonal migration timescales is mortality at depth of hibernating zooplankton particularly in high latitude regions^{57,58}, sequestering carbon to depths >500 m depth. Global extrapolation of seasonal lipid pump fluxes, along with the over-wintering mortality flux is problematic due to difficulties in sampling and generalizing across distinct regional mechanisms³⁰ (S-Table 1).

The potential for double accounting

The export flux from the BGP is mediated by sinking particles, whereas PIPs can provide additional pathways for all particle classes, from suspended to sinking, to exit the surface ocean (Fig. 1). Thus, there is potential overlap between particles delivered from the surface ocean to depth via the BGP and by injection from PIPs. Such overlap – termed here as

224 ‘double-accounting’ – may occur where particles associated with the BGP and a PIP are
 225 difficult to distinguish and hence could be attributed to more than one pump (Fig. 1). At
 226 depth, transformations such as aggregation alter particle characteristics, including size and
 227 sinking rate, and hence particles injected by the PIPs can join the sinking flux usually
 228 attributed the BGP (Fig. 1). A further factor that introduces overlap between the BGP and
 229 PIPs results from the inclusion, for historical reasons⁵⁹, of one component of the mesopelagic
 230 migration pump (diurnal migration by mesozooplankton) into the 1D sampling framework of
 231 the BGP, while other components (e.g. patchier diurnal migration by larger mesopelagic
 232 carnivores⁵) are not. Hence double-accounting can confound our understanding of the
 233 relative importance of PIPs to ocean carbon storage.

234 Is it possible to tease apart these areas of overlap? Forty years study of the BGP has
 235 uncovered a complex biogeochemical system with multiple drivers and distinguishing
 236 characteristics^{11,60}. This body of research helps to frame the differences and similarities
 237 between particles delivered to depth by PIP’s and those settling via the BGP. Each PIP is
 238 distinct with respect to its combination of injected particle type (suspended cells to faecal
 239 pellets of large mesopelagic migrants), the timing and depth of injection (Fig. 2a-b), and
 240 associated particle transformations (aggregation/disaggregation)^{11,12,61}. Additionally, the
 241 subsurface “fate” of particles (i.e. where they remineralize), which determines the longevity
 242 of carbon sequestration, is driven by the complex interplay between these properties and
 243 transformations^{12,60,61}: Particle composition and architecture set their sinking speed, while
 244 myriad processes that are biologically- (microbes/zooplankton) and physically-mediated
 245 (fragmentation/ disaggregation)^{12,62-64} decompose and repackage them over depth (Fig. 1).
 246 Therefore, particle fate provides another avenue to distinguish the contributions of PIPs from
 247 the BGP.

248 To date, evidence on the subsurface fate of injected particles has been largely indirect^{27,28,49}.
249 Surveys of eddy-subduction pumps suggest that injected particles may be remineralised at
250 depths <200 m, based on ammonium peaks⁴⁹, time-series of biogeochemical gradients²⁸, or
251 particle modelling studies²⁷. In the NE Atlantic, reported high rates of particle
252 remineralisation (glider-based biogeochemical gradients) must be reconciled with concurrent
253 evidence of coincident, coherent chlorophyll plumes at depths >300 m indicative of
254 subducted viable phytoplankton²⁸. This glider-based time-series reveals pronounced
255 patchiness²⁸ suggesting that inference of the fate of injected particles even from state-of-the-
256 art observations is challenging.

257 Better constraining the contribution of each PIP to mesopelagic carbon budgets will require
258 characterisation of the injected particle assemblage and their transformations during
259 downwards transport^{12,65-68}. Particle aggregation in PIPs may be driven by
260 convergence/subduction⁶⁹⁻⁷⁰ and/or differential sinking^{65,67}, potentially leading to altered
261 modes of subsurface transport (Fig. 1). BGC-Argo profile observations allow quantification
262 of the size, type, seasonal succession, and penetration depths of particles injected by the
263 mixed-layer pump³⁶ – properties which have the potential to differentiate them from fast-
264 sinking particles (i.e., BGP) whose distinctive ‘spiky’ bio-optical signature is readily detected
265 using multiple sensors⁷¹ (S-Figs. 2 and 3). Advances in bio-optics are already making cryptic
266 signatures associated with slow-sinking particles and zooplankton vertical migration less
267 opaque, lessening the possibility of double-accounting. Such double-accounting may be
268 avoided through the identification of unique characteristics of pumps including seasonality
269 (Fig. 2a), distinctive regional features³⁰, or multi-variate oceanographic diagnostics⁷².

270

271

Carbon sequestration potential

The potential carbon sequestration by each PIP can be quantified as the product of their carbon injection rate and their sequestration timescale, i.e. time until remineralised carbon is returned to the surface (see Supplementary Methods). This timescale is determined both by the injection depth of particles and their eventual fate, i.e. the degree to which they sink or circulate through the ocean before remineralising to CO₂. In general, deeper particle injection and rapid sinking translates to longer carbon sequestration because the “passage time” from the ocean interior to the surface increases with depth (Fig. 2b). Here, we assemble prior estimates of carbon injection rate and depth (S-Table 1), along with new modelling projections (Fig. 2), to estimate carbon sequestration by each PIP and assess their significance relative to the BGP.

Some targeted studies provide concurrent estimates of carbon injection by individual PIPs and the BGP^{27,28}, whereas others^{30,54,57,58} facilitate comparison of regional-scale PIP fluxes with independent estimates of the BGP. Both approaches reveal that PIPs each have the potential to contribute significant rates of POC export. The reported upper bounds of global PIP estimates summed together is 8.7 Pg C yr⁻¹, which is comparable to the BGP export flux (Table S1). This comprises 1.1-2.1 Pg C yr⁻¹ for the large-scale/mesoscale physical pumps (also includes DOC^{22,23}), and 0.25-1.0, 0.9-3.6 and (-0.09) to 2.0 Pg C yr⁻¹ from the lipid seasonal, mesopelagic migration, and eddy-subduction pumps, respectively (Fig. 2c). Thus, their cumulative contribution may be as much as ~40% of total particle export (i.e., BGP+PIPs) suggesting considerable potential to resolve the imbalances reported for mesopelagic carbon demand¹⁷, between nutrient and carbon export budgets¹⁵, and to lessen the variability between model estimates of global carbon sequestration (S-Table 1).

We estimated the sequestration timescales for each PIP based on the “passage time” from the injection depth to the surface in an observationally-constrained ocean circulation model¹⁴. Particles injected at the depth of the wintertime mixed-layer by the large-scale physical pumps (mixed-layer and subduction) result in sequestration for 25-100 years, assuming subduction occurs before re-entrainment next winter. In turn, deeper injection by the eddy subduction pump (up to 450 m), mesopelagic migration pump (up to 600 m), and seasonal lipid pump (up to 1400 m) translates to sequestration timescales up to 150, 250, and 500 years respectively (Fig. 2b). These timescales will increase if it is assumed that sinking rather than suspended particles are injected, which remineralise deeper than the injection horizon (see Supplementary Methods).

Given the wide-ranging estimates of carbon injection rate (Fig. 2c) and depth (Fig. 2b) for each PIP, oceanic carbon sequestration by these mechanisms cannot be estimated with precision (Fig. 2d). However, choosing central values from the reported ranges of each property allows a first order comparison between PIPs and the BGP. The mesopelagic migration pump emerges as the most significant PIP, potentially storing ~60% as much carbon as the BGP in the ocean interior if large, sinking particles (i.e. faecal pellets) are injected. The C storage potential of the seasonal lipid, eddy-subduction and large subduction pumps are ~20%, 10% and 5% of the BGP respectively, assuming each injects suspended particles. The latter small net value is due to offsetting of subduction by strong obduction (upward transport of water parcels) in the equatorial oceans³⁹. Based on these central values (Fig. 2d), it is likely that the reservoir of respired carbon in the ocean interior contributed by the PIPs approaches that contributed by the BGP, and may therefore help to close global-scale mesopelagic carbon budgets^{15,16}.

Tracer constraints on the fate of exported carbon

Oceanic carbon sequestration by the BGP and wide-ranging biophysical mechanisms that inject biogenic particles to depth depends critically on the fate of exported carbon (Fig. 2). However, at present tracing the remineralisation of particles (regardless of their export pathway) as they settle and circulate through the global ocean remains a logistical challenge, due to the difficulties of deep-water particle sampling. Recently, new methods have used 3D ocean data assimilation models to leverage geochemical “remineralisation tracers” including oxygen and nutrients. These tracers integrate particle remineralisation signatures over long timescales, and their global distributions are characterised by orders of magnitude more observations than are available for particles^{16,31,73}. Two distinct approaches have been applied. The first diagnoses remineralisation rates directly from phosphate accumulation along transport pathways in a circulation model, and reconstructs particulate flux profiles required to explain the global distribution of remineralised phosphate³¹. The second assimilates geochemical and satellite data into mechanistic biogeochemical models to optimise key particle flux parameters, yielding mechanistic insights while leveraging the observations less directly⁷³.

Both approaches have yielded similar results and provide evidence for regional variability in particle flux attenuation, with the flux attenuating slowly at high latitudes and quickly in subtropical gyres, while the tropics lie between these two extremes (Fig. 3a). These simulations reveal that carbon exported from high latitude and tropical surface waters is sequestered longer in the oceans’ interior than carbon exported in the oligotrophic gyres (Figure 3b), with important implications for feedbacks between the particle export and global climate. Atmospheric pCO₂ is likely more sensitive to past changes in high latitude export than previously recognised⁸, and the future expansion of subtropical habitats⁹ may result in less efficient (although not currently quantifiable) carbon sequestration in a warming world.

Regional variations in particle flux attenuation have largely been interpreted in terms of the balance between decomposition and sinking rates³². A likely explanation for the diagnosed latitudinal pattern is the temperature-dependent metabolism of heterotrophs responsible for particle decomposition^{32,73}, although variations in particle size and/or ballast are valid alternatives⁷³. There may also be a secondary effect of oxygen, with decomposition slowing in anoxic zones^{73,74}, and even hypoxic waters due to anaerobic microenvironment formation in particles⁷⁵.

To some degree, model-derived particle flux profiles may also reflect the relative magnitude of different export pathways (PIPs and BGP), which vary in the injection depth and nature of particles they supply, since geochemical tracers integrate the effects of all export mechanisms. Deep injection by PIPs would result in slower flux attenuation over depth, whereas injection of suspended particles that remineralise shallower in the water column would be diagnosed as rapid flux attenuation. Predicting future changes in ocean carbon sequestration will require a better understanding of the contribution of injection versus remineralisation processes to sequestration efficiency (Fig. 3b), given the different environmental sensitivity of these processes.

The need for prediction motivates development of new techniques to distinguish particle flux associated with the BGP and each PIP. Particle stoichiometry (i.e., C:N:P) may be central to identifying particular mechanisms that decouple their export. For example, diagnosing oxygen consumption between 500-1500 m (depth of zooplankton hibernation) without concomitant nutrient accumulation would point to carbon export by the seasonal lipid pump³⁰. Alternatively, diagnosing seasonal cycles of nutrient accumulation and oxygen consumption rates would help distinguish remineralisation of particles exported by physical pumps versus particle settling, which should exhibit distinct seasonality (Fig. 2a). This approach may soon

be possible given the burgeoning spatial/temporal resolution of tracer data provided by BGC-Argo floats (S-Figure 1), and emerging float sensor technology (S-Table 2).

Extrapolation – towards a 4D view of particle export

Improving the accuracy of the initial estimates of the magnitude of carbon sequestration presented in Figure 2d requires the development of a 4D picture of particle flux and storage in the oceans' interior. It is clear from our synthesis of PIP mechanisms that multiple scales, from sub-mesoscale to basin, must be accommodated if PIPs are to be assembled, first spatially and then temporally, into a complete 4D picture. Again, lessons on how to approach such upscaling can be gleaned from BGP research which imprinted both spatial and seasonal signatures (satellite remote-sensing/modelling)²⁶ onto short-term (days-weeks) observations taken at specific sites (Box 1). The timescales and lifetimes of features such as submesoscale eddies/fronts or seasonal mesopelagic export signatures (Fig. 2a) must be characterized to define the temporal footprint of each PIP and move towards a 4D viewpoint. This framework must be linked to the seasonality of pelagic particle production to assess if there is distinctive period for the subduction of significant stocks of these upper ocean particles (Fig. 2a). For example, it is well-established that submesoscale dynamics are strongly seasonal, with stronger and deeper penetration during winter than summer⁷⁶.

Some published approaches towards extrapolating PIP's globally, and to climatological time scales, are outlined in S-Table 1. The identification of the specific drivers of each PIP mechanism should help improve modelling and hence extrapolation. We advocate the utility of explicitly incorporating the different PIP mechanisms into predictive, mechanistic models as a means to extrapolate PIPs into 4D. In the case of the extrapolation of the submesoscale eddy subduction PIP, increasing the model grid resolution to incorporate these features is

necessary and is now achievable in regional configurations^{77,78}. In contrast, other physically-mediated PIPs such as the large-scale subduction and mixed-layer pumps are already represented in global models, and so their extrapolation requires the development of diagnostics to enable the simulated POC/DOC distributions to be better evaluated against observations²³. At present, the biologically-mediated PIPs are not incorporated into state-of-the-art biogeochemical models^{9,14,31,77,78}. While simulating animal behaviour at the global scale remains a grand challenge in ocean modelling, simple parameterisations have been developed to predict the geochemical effect of the mesopelagic migrant pump⁶, which might be further expanded to incorporate hibernation and therefore the seasonal lipid pump. It is only very recently that diel vertical migration has been incorporated for the first time in a global ocean general circulation model and used to estimate the associated flux of carbon at the global scale (see Aumont et al. in S-Table 1). Although promising, this approach remains challenging because it is based on a computationally-intensive, end-to-end ecosystem model in which all trophic levels from phytoplankton to top predators interact.

Transforming our view of ocean carbon export

Our synthesis of physically- and biologically-mediated PIPs reveals that they are directly transporting significant stocks of biogenic particles to depth, of a cumulative magnitude that may be equivalent to the carbon storage of the BGP. The potential of PIPs to make a major contribution to the ocean carbon budget must now be explored in more detail, commencing with those PIPs that are most likely to contribute to carbon sequestration. Synthesising estimates of particle export, injection depth, and circulation timescales reveals that the mesopelagic migrant pump has the greatest potential to contribute to carbon sequestration, followed by the seasonal lipid pump and the various physical pumps (Fig. 2d). In the case of

the seasonal lipid pump, its geographical realm of influence is already established³⁰, whereas less is known about the regional contributions of the mesopelagic migrant pump⁵.

For all PIPs, the most pressing research issue – needed to address double-accounting issues and improve estimates of carbon sequestration – is to better understand the mechanisms of particle transformations^{17,65-68} (Fig. 1) within a 4D framework. Specifically, the fate of exported particles between their injection depth and the permanent pycnocline remains poorly constrained. A first step will be improved particle characterisation, in particular the ability to distinguish zooplankton from other particle types, and to aggregate Particle Size Distribution (PSD) profiles through the development and application of new sensors (S-Table 2). Future development of acoustic and imaging technologies⁷⁹ must be deployed on a range of platforms from ships (i.e., calibration) to an array of long-lived (i.e., years), geographically-diverse BGC-Argo floats. These developments towards improving particle characterisation will reduce the likelihood of double-accounting. Moreover, the alignment of BGC-Argo deployments (Box 1) with the characteristic space and time scales of PIPs will enable better quantification of the role of patchiness in driving observed local/regional hotspots in biological PIPs^{30,54,56}. In time, following the development and testing of a Coastal-Argo platform, they can also be deployed to coastal and shelf seas to explore the role of PIPs in these regions (S-Table 2).

The way forward in refining estimates of the contribution of PIPs in closing the ocean carbon budget¹⁵⁻¹⁷ also requires leveraging advancements in ocean biogeochemical modelling.

Models are valuable testbeds to probe the sensitivity of carbon storage mechanisms, and guide future observations. For example, model sensitivity analyses point to the pivotal role of PSD in determining the fate of exported carbon^{31,73}, but the processes that set the PSD of exported particles and its evolution over depth remain crudely parameterized. Developing robust models of particle transformations between multiple size classes, and incorporating

441 them into general circulation models, will allow us to trace the fate of particles injected by
442 different PIPS and dissect their contribution to carbon sequestration, while avoiding double-
443 accounting issues.

444 Inverse methods that can assimilate PSD fields from new BGC-Argo technologies⁸⁰ will
445 allow models to “learn” from the data, further refining them to best reflect the real ocean.
446 Furthermore, downscaling of physical models is essential to simulate the locations of PIP
447 injections in support of observational programmes such as high resolution altimetry⁸¹, and the
448 integration of detailed particle transformations into submesoscale models⁸².

449 To transform the comprehension of particle export from one- to three- and eventually four-
450 dimensions, machine learning approaches⁸³ will need to be employed, which can be trained to
451 predict unknown variables such as particle flux from better sampled variables. Approaches
452 like artificial neural networks⁸⁴, will enable and enhance the upscaling of local/regional
453 datasets needed to provide more robust extrapolation^{85,86} to depth, regionally, and annually of
454 each PIP. This upscaling is essential to refine estimates of the contribution of each PIP to
455 carbon sequestration. BGC-Argo datasets will also eventually be combined with new satellite
456 products such as hyperspectrally-resolved ocean colour observations of biology processes⁸⁷
457 and submesoscale characterisation of sea level using high-resolution altimetry⁸¹.

458 Satellite and water-column remote-sensing, along with targeted process studies, will yield
459 expansive datasets that can be assimilated into regional and global models of ever increasing
460 realism and resolution. Together, these approaches will lead towards a robust, four-
461 dimensional view of carbon sequestration by the ocean’s multi-faceted bio-physical particle
462 pumps.

Figure 1 Interplay between particle characteristics, mode of export (BGP or PIP), delivery depth and larger scale ocean circulation for a range of pumps. In the upper panel, the box (top left) represents mixed-layer particle types, which either form large sinking particles (i.e., within the BGP, such as faecal pellets, marine snow) or are injected to depth (i.e., PIPs, suspended/ slow-settling heterogeneous particles and cells (i.e., including healthy, slow-sinking phytoplankton⁸⁸)). The vertical yellow arrow signifies the BGP; black lines physically mediated PIPs; and purple lines biologically mediated PIPs. The delivery rates of particles to subsurface strata (in m d^{-1} , ? denotes not known) are presented for each pump. Patchiness in the distribution of vertically-migrating animals (top right) plays a role in driving three-dimensional particle delivery to depth^{89,89}, and is denoted by different fish or copepod stocks in the upper ocean. The box (middle left) presents different particle transformations central to the BGP¹², but whose role is not known so far for PIPs. They include microbial solubilisation, aggregation (marine snow denoted by aggregation I; heterogeneous faecally-dominated aggregates (aggregation II) and/or dissaggregation¹⁸ to form/break down heterogeneous particles (hatched brown symbols). In the lower panel, depths in parentheses are the reported delivery depths, with the BGP (and some PIPs) exporting some particles to the sea floor. Blue curved arrows represent transport of subsurface material along downward-sloping isopycnals (white dashed lines). Major unknowns include whether physical transport by PIPs can cause particle aggregation (signified by ? in the middle panel below subduction pump, and also applicable for the mixed-layer pump) and hence alter their mode of injection towards gravitational settling (i.e., the BGP). Other unknowns include the potential ballasting role of small mineral particles such as aerosol dust for PIPs.

Figure 2 Carbon export and storage by PIPs compared to the BGP. **a)** Idealised seasonality of the PIPs for regions that exhibit strong seasonality, where a Spring Bloom dominates C export by the BGP (dark blue line). Coloured bars indicate season of peak C export by the PIPs (acronyms defined in legend). Note the large-scale physical pump should be strongest when mixed layers are deepest, but is likely operative all year (dashed line). **b)** Sequestration efficiency of the PIPs. Black lines represent the global-mean sequestration timescale for carbon injected at a given depth, defined as the time for remineralised carbon to circulate back to the ocean surface, computed in a data-constrained circulation model (see S-Methods). Solid line assumes that particles are suspended, so remineralisation occurs at the injection depth, whereas dashed line assumes that particles are sinking and remineralise over depth (see Methods). Colored bars show injection depth range of the BGP and PIPs. The efficiency of each pump is defined as the sequestration time from its injection depth. **c)** Strength of the pump mechanisms, defined as their rate of carbon export or injection (see Table S1). “All PIPs” refers to the sum of the five individual PIPs **d)** Ocean carbon storage by each pump, defined as the product of the strength (**c**) and efficiency (**b**). Two scenarios are shown for each PIP, using the sequestration time for suspended (circles) and sinking (square) particles, whereas the BGP is assumed to export only sinking particles. For the sum of PIPs, we present a “most likely” scenario, in which the migrant pump injects sinking particles (faecal pellets), and all other PIPs inject suspended particles (triangle).

Figure 3. Fate of exported organic matter constrained in models from geochemical remineralisation tracers. a) Organic matter flux over depth (normalised to flux at the base of the euphotic zone), averaged across subtropics, tropics, and high latitude regions (as defined³¹). Lines show flux profiles from a mechanistic model⁷³ that is optimised to match geochemical constraints (shading represents the range between 12 model configurations); circles represent the transfer efficiency diagnosed directly from nutrient accumulation in an ocean circulation model³¹. **b)** Sequestration time of exported carbon. The spatial pattern reflects both variability in the particle flux attenuation (**a**), and patterns of large-scale circulation. The thin black lines separates regions of efficient (>100 years) and inefficient (<100 years) carbon sequestration.

Box 1 Approaches used to investigate downward particle export, from the BGP to PIPs.

The BGP is quantified in a biologically-patchy upper ocean (green filaments) using ship-based surface sampling (particle production) and subsurface particle interception by sediment traps, most recently neutrally-buoyant traps downstream of particle source regions (orange instruments, a). This coupled surface-subsurface sampling strategy is logistically-complex, temporally- and spatially-restricted (i.e., represented here by a “statistical funnel”^{91,92}, see a), and hence provides a ‘1D’ view of particle export that is extrapolated to the basin scale using satellite observations and/or modelling. This ‘1D’ viewpoint cannot measure the PIPs presented in b) to e), and is contrasted in a) with the 4D view^{29,93} obtained by an ensemble of BGC-Argo floats (white instruments).

(b) the mixed-layer pump, in which particles are detrained when the pycnocline (blue dashed line) shallows, can be addressed regionally through backscattering (a proxy for POC) profiles measured by BGC-Argo floats³⁶, or globally using satellite surface-ocean backscattering and Argo/BGC-Argo (density/backscattering) vertical profiles³². c) the seasonal lipid pump is quantified using surveys of overwintering copepods at depths below the permanent pycnocline and subsequent scaling of their lipid-enriched biomass in carbon content³³. d) the eddy subduction pump can be quantified using gliders (pink instruments) and subsequent modelling³¹, BGC-Argo floats (bio-optics/oxygen/physics)⁹³ or surveys based on multiple POC profiles in conjunction with coupled models (regional circulation/particle dynamics)^{30,49}. e) quantification of the mesopelagic migrant pump (active diel transport of carbon by mid-water biota, denoted by moon and sun symbols) requires mid-water trawl surveys along with metabolic modelling^{54,55}. Some multidisciplinary studies^{30,31,49} have combined these approaches to cross-compare export flux from the BGP (green arrows (d)) and the eddy subduction pump (purple arrows represent subsurface particle maxima recorded at the eddy periphery³¹). Note, the large-scale subduction pump²³ is not presented here.
