Abstract

As in most industrial cases, the expansion of premixed flames in Spark-Ignition (SI) engines is strongly affected by turbulence flow fields. However, as the flame radius and curvature are non-negligible during combustion development, the global stretch effect can drastically change the turbulent flame propagation speed. In this paper, spherical turbulent premixed flames were studied inside a constant-volume vessel for a wide range of air-isooctane mixtures, initial turbulent intensities and pressures by using simultaneously Mie scattering tomography and 2-View Schlieren imaging. The comparison between different radii enabled non-convected flames with a global spherical shape to be selected and the validity of a correction factor, first introduced by Bradley et al., was assessed. A set of turbulent flame speeds was obtained and the evolution as a function of the global stretch rate was analyzed. Various turbulent flame speed definitions were also evaluated on two different datasets.

Keywords

Turbulent flame speed, spherical expanding flame, iso-octane-air mixture

Introduction

Although premixed turbulent combustion has been studied for over 40 years, it remains a significant problem for practical combustion processes such as those found in stationary power gas turbines, spark-ignition engines, and explosions. The problem is particularly crucial due to the use or future use of premixed turbulent combustion in increasingly drastic conditions in terms of pressure, temperature and diluted environment. As underlined by Verma and Lipatnikov (Verma and Lipatnikov 2016) and Lawes et al. (Lawes *et al.* 2012), the notion of turbulent flame speed, S_t or burning velocity, U_t remains unresolved, despite the large amount of data available. Matalon and Creta (Matalon and Creta 2012) consider that S_t represents the mean propagation speed of a premixed flame in a statistical steady state within a turbulent field, similar to the laminar flame speed. In fact, depending on the experimental set-up (Bunsen burner, flat burner, spherical vessel) and measurement techniques (Schlieren, Mie or LIF tomography, pressure sensors), the data are more or less sparse. In the case of SI engine applications, the burning speed can be estimated in an optical engine (Aleiferis et al. (Aleiferis *et al.* 2013), Mounaïm-Rousselle et al. (Mounaïm-Rousselle *et al.* 2013)). While some studies show good agreement, at least qualitatively, about the evolution of the burning velocity as a function of the thermodynamic and turbulent parameters, it is still challenging to conduct measurements in this kind of experiment due to the strong cyclic variations of the flow and the flame ignition/propagation itself. Therefore, to reach similar conditions to those of an SI engine, a turbulent spherical vessel remains the best apparatus to provide accurate data on turbulent flame speed and thus to validate models. The use of a fan-stirred vessel can allow uniform and isotropic turbulence in the central measurement region with less variability. However, there is currently no consensus on the optimal technique to provide ‘good’ or ‘real’ estimates of the turbulent burning velocity from flame radius measurements (Lipatnikov and Chomiak 2002). Bradley et al. (Bradley *et al.* 2003) did an interesting analysis by comparing turbulent burning velocities estimated from different flame radius definitions. They concluded that Schlieren images remain the most convenient way to provide accurate experimental data. The Schlieren technique is a ‘real’ non-intrusive optical technique, contrary to Mie scattering or LIF tomography that require droplet or tracer seeding. Most recent studies on this kind

of set-up are based on Schlieren images (Goulhier *et al.* (Goulhier *et al.* 2017), Lawes *et al.* (Lawes *et al.* 2012), Bagdanavicius *et al.* (Bagdanavicius *et al.* 2015), Wu *et al.* (Wu *et al.* 2015)).

In the case of expanding turbulent flames, however, the acceleration mechanism is more complex than in a burner configuration. The turbulent flame front is affected not only by local stretch rates related to the wrinkling of the flame front due to the turbulent scales, but also by the mean global stretch rate, as in the laminar case (Bradley *et al.* 2003). Several recent studies (Gillespie *et al.* 2000, Renou and Boukhalfa 2001, Bradley *et al.* 2003, Chaudhuri *et al.* 2012, 2015, Brequigny, Halter, and Mounaïm-Rousselle 2016) focused on the flame response to stretch for different fuels, different Lewis numbers (Le) and different turbulent and pressure conditions. Lipatnikov and Chomiak (Lipatnikov and Chomiak 2002) demonstrated the importance of considering the effects of large scale stretching to obtain accurate data from expanding spherical flames.

The objective of the present paper is to provide new experimental turbulent flame speed measurements in a fan-stirred constant-volume combustion chamber for different iso-octane/air mixtures. The accuracy of the measurements obtained with the Schlieren technique is evaluated by comparing results from simultaneous Mie-scattering tomography. A 2-view Schlieren was set-up to guarantee the selection of flames that propagate globally in a spherical shape in order to avoid measurement bias in the flame radius determination. As iso-octane is an usual gasoline surrogate, it was necessary to provide new data to supplement the limited data available in the literature (Lawes *et al.* 2012) for different initial pressures and turbulent intensities in order to improve the different models/relationships proposed in (Kobayashi *et al.* 1998, Bradley *et al.* 2011a, Chaudhuri *et al.* 2012, 2015). Moreover, the response of an iso-octane mixture to stretch is interesting as Le evolves versus the equivalence ratio (Brequigny, Halter, Mounaïm-Rousselle, *et al.* 2016).

Experimental set-up

a. Combustion vessel

Experiments were conducted in a high-pressure/high-temperature 200 mm diameter spherical vessel used for both laminar and turbulent premixed flame propagation investigations (Galmiche *et al.* 2012, Brequigny, Halter, and Mounaïm-Rousselle 2016, Brequigny, Halter, Mounaïm-Rousselle, *et al.* 2016, Endouard *et al.* 2016). The vessel is equipped with four optical quartz windows providing optical access to implement optical diagnostics. A heater wire resistance located on the outer surface of the sphere is used to heat the initial gases up to a maximum temperature of 473K. The temperature fluctuation of the mixture is estimated to be less than 2K for the initial target temperature. Initial pressure inside the vessel is limited to 10 bar with a maximum deviation between the effective and the set-point initial pressure of about 3%. The isooctane/air mixture is introduced in the vessel by means of flowmeters. For more details about the preparation of the reactive mixture see (Galmiche *et al.* 2012). The mixture is ignited by a spark produced between two 0.5 mm diameter tungsten electrodes with a coil charge time of 3 ms for all cases.

Turbulence is generated by six identical four-blade fans (40 mm diameter) located in a regular octahedral configuration, close to the wall of the vessel. The fans direct the flow towards the center of the vessel and run continuously during combustion propagation. Each fan speed can be accurately adjusted between 1000 and 17000 rpm with an accuracy of $\pm 0.1\%$.

In previous work (Galmiche *et al.* 2013), the turbulent flow was fully characterized in non-reactive conditions and found to be homogeneous and isotropic in a central portion measuring 40 mm in diameter. The turbulence intensity is proportional to the rotational fan speed with a constant integral length scale, L_T , of 3.4 mm.

b. High speed techniques and image post-processing

First, High Speed (HS) Schlieren imaging and Mie scattering tomography were simultaneously set up (Fig. 1) to assess the validity of the correction proposed by (Bradley *et al.* 2003) that is needed for Schlieren images in order to avoid overestimation of the flame radius due to flame projection. The 2-

View Schlieren technique was implemented in order to select flames that keep a global spherical shape during propagation. Each Schlieren pathway was made by using a LED (CBT120), coupled with a 1 mm pinhole to guarantee a point source and two convex metallic mirrors (864 mm focal length). At the focal point of the second mirror, a 0.5 mm dot is placed and two lenses (200 mm and 160 mm) focus images directly onto the CMOS chip. With this arrangement, the two views can be simultaneously recorded with only one HS camera (Phantom v1610) at full resolution (1024x800 pixels²) and a magnification ratio of 0.1 mm per pixel. For Mie scattering tomography, a laser sheet produced by a HS Nd-Yag laser (Quantronix dual-Hawk HP) passes between the two electrodes with a 4° tilt angle to prevent any interaction with the Schlieren arrangement. A second HS camera mounted with a Scheimpflug adapter and a 200 mm Nikon macro-lens records Mie scattering images (from silicon oil seeding droplets) with a delay of only 5μs relative to the Schlieren images to prevent any light interaction.

c. Experimental conditions

All the experimental conditions investigated are summarized in Table 1. The initial temperature was 423K, kept constant for all conditions to ensure both full vaporization and stable ignition in all cases of turbulence and dilution. For some cases (symbol ‘*’), 7.5% EGR dilution was added to the mixture to provide different values of S_L^0 without strongly affecting the stretch sensitivity of the mixture. The dilution by Burnt Gases was simulated by a 12.4% CO₂, 14% H₂O and 73.6 % N₂ mixture (% in volume). The unstretched laminar burning velocity, S_L^0 and the Markstein length, L_b , shown in Table 1 were obtained by using data and correlations from previous studies (Galmiche *et al.* 2012, Endouard *et al.* 2016). Lewis numbers, Le were calculated using the method of Bechtold and Matalon (Bechtold and Matalon 2001).

All flames can be considered to lie between the thin reaction zone and the corrugated flamelet zone, in the flamelet regime on the Peters-Borghi diagram (Borghi 1984, Peters 1988) in Fig. 3. Ka , the Karlovitz stretch number was calculated with the following expression $Ka = (\delta_L/L_T)^{1/2}(u'/S_L^0)^{3/2}$ with L_T the integral length scale and δ_L the laminar flame thickness. Ma_b was determined by dividing the experimental L_b by the laminar flame thickness, δ_L , calculated as $D_{th}/\rho_u c_p S_L^0$ with D_{th} the thermal diffusivity, ρ_u the unburnt gas density, and c_p the heat capacity at constant pressure. Ma_t was

calculated as $\ln(\rho_u/\rho_b)/4$ (Lipatnikov and Chomiak 2007) (with ρ_b the burnt gas density) to parametrize the large-scale stretching of turbulent flames (Bradley *et al.* 2011b). Finally the Damkohler number was obtained using the expression $(L_T/\delta_L) * (u'/S_L^0)$. Isooctane-air mixtures were already studied in (Lawes *et al.* 2012) and can be compared with the present work. Lawes *et al.* carried out their experiments with a lower temperature (360 K) in conditions of pressure similar to the present work: mainly 0.5 MPa (with a few additional tests at 0.1 and 1 MPa), equivalence ratio from 0.8 to 1.4 and turbulence intensities of 0.5, 1, 2, 4 and 6 m/s. The present work extend the database first at 0.1 MPa, second with more turbulent intensities ranging from 0.5 to 2.7 m/s and last with a lower integral length scale: 3.4 mm for the present study vs. 20 mm for (Lawes *et al.* 2012). The integral length scale of the present vessel is therefore closer to those observed in automotive Spark-Ignition engine, i.e. about 1.4 mm in (Mounaïm-Rousselle *et al.* 2013). For the sake of comparison the data of Lawes *et al.* at 0.1 and 0.5 MPa, equivalence ratio from 0.8 to 1.4 and all turbulence intensities were reported in the Peters-Borghi diagram in Fig. 3.

Table 1 – Turbulent and flame parameters for all investigated conditions. (* indicates that 7.5% of the total mixture is synthetic EGR dilutant).

Results and discussion

b. Determination of turbulent flame speed

Schlieren and tomographic images were post-processed using Matlab software to extract the flame contour as can be seen in Figure 2. All radii are given with an uncertainty of +/- 0.2 mm at 1 bar and +/- 0.5 mm at 5 bar.

Bradley et al. (Bradley *et al.* 2003) defined a reference radius R_v , such that the burnt gas volume outside the sphere of this radius is equal to the unburnt gas volume inside it, to estimate the turbulent burning velocity from a planar flame sheet. R_v corresponds to the radius from a contour at the mean progress variable, $\tilde{c} = 0.5$. It is a key parameter, since for the spherical surface defined by it:

- the mass turbulent burning velocity and entrainment turbulent burning velocity are equal
- the turbulent flame propagation speed is equal to the turbulent burning velocity multiplied by the density ratio.

On the other hand, as the Schlieren flame contour contains both burned and unburned gases, the radius calculated from it, R_{Sch} , is not equal to R_v . Bradley et al. suggested the following empirical linear equation:

$$R_v = C \cdot R_{Sch} + B \quad (1)$$

With C and B , constant coefficients experimentally determined and suggested as 0.9 and -2.1 respectively by Bradley et al. (Bradley *et al.* 2003).

As the turbulent burning velocity can be estimated by $U_t = \frac{\rho_b}{\rho_u} \cdot \frac{dR_v}{dt}$ with ρ_u and ρ_b respectively the unburnt and burnt gas density, it can be written :

$$U_t = \frac{\rho_b}{\rho_u} \cdot C \cdot \frac{dR_{Sch}}{dt} = \frac{\rho_b}{\rho_u} C \cdot S_{Sch} \quad (2)$$

with S_{Sch} , the turbulent propagation flame speed estimated from Schlieren technique and C the constant introduced in Eq. (1).

Since the flame is considered spherical, $R_{Sch} = \sqrt{A_{Sch}/\pi}$ and $R_{Tomo} = \sqrt{A_{Tomo}/\pi}$ are respectively the flame radii determined from Schlieren and tomographic images based on the burnt gas surface, A (Sch and Tomo respectively). The reference radius, R_v is considered to be equal to R_{Tomo} . As a 2-View Schlieren technique was set up, another radius was also estimated, based on the estimate of the flame volume: $R_{V,Sch} = (3V_S/4\pi)^{1/3}$. As shown in Fig. 2, from the side and front view Schlieren images, the flame volume was determined by integrating the surface of the ellipses as a function of the z direction. These ellipses, indicated in grey in Figure 2, were fitted through four points defined from the two Schlieren contour projections.

An example is given in Figure 4, where the average values of R_{Sch} , $R_{V,Sch}$ and R_{Tomo} are plotted versus time for a stoichiometric mixture. First, as expected, no difference is distinguishable between the radius obtained from 2-View or 1-View Schlieren imaging, which confirms the sphericity of the flames and shows that the 1-View Schlieren technique is sufficient. Second, for all examples, R_{Tomo} are smaller than R_{Sch} , due to the 2D cut for the tomography and the 3D projection for Schlieren images. The reference radius, R_v , estimated from Eq.1 by using the constant values of Bradley et al. is added. In the first part of the flame development, R_v is smaller than R_{Tomo} until 6ms. Then, from 6 to 9ms the two radii display similar values before R_v becomes greater than R_{Tomo} . The constant values determined by Bradley et al. were established for a set of 37 propane-air flame tests by considering flame radii between 2 and 40 mm. Since the experimental conditions in the present work are comparable to those investigated in (Bradley *et al.* 2003), the discrepancies observed between R_v and

R_{Tomo} could be due to the difference in radius range (less than 30 mm) or the fuel itself, which affects the flame front wrinkling response to turbulence.

Figure 4 –Temporal evolution of different average radii at $P_0 = 0.1$ MPa, $\phi = 1$, $T = 423$ K, $u' = 1.04$ m/s.

Hence, the constant C , also called the correction factor, was recalculated for the conditions (shaded in grey in Table 1) as

$$C = \left\langle \frac{dR_{A,Tomo}}{dR_{A,Sch}} \right\rangle_{propagation\ duration\ time} \quad (3)$$

It should be mentioned that the 2-View Schlieren technique was only used to verify to what extent the flame can be considered spherical and also the effect of spark electrodes on its development. As shown in Fig. 4, for one example, the radius determined by the 2-View ($R_{V,Sch}$) or 1-View (R_{Sch}) Schlieren set-up was similar, with less than 3% difference. Therefore, in this study, only 1-View Schlieren imaging was used. For the other conditions only the 1-View Schlieren technique was used. For all conditions, between 8 and 10 tests were performed to provide sufficient data to ensure accuracy of the average. The variations on the flame speed were less than 5% and were not related to the pressure.

All the values obtained for the correction factor were between 0.65 and 0.8, i.e. below 0.9 (Bradley *et al.* 2003), as can be seen in Figure 5. These values are in a good agreement with a more recent study by Bradley *et al.* (Bradley *et al.*, 2011) where the values of the ratio R_v/R_{Sch} (as defined at the beginning of the present section) lay between 0.79 and 0.75. It is interesting to remind that the integral

length scale in the ‘Leeds’ vessel is higher than the one of the present vessel (20 mm vs 3.4 mm). As a result, the integral length scale seems to be not so impacting for the correction factor C . However the correction factor appears to decrease with the increase in u'/S_L^0 . The trend seems to be valid because if one considers the values at $u'/S_L^0 = 1.33$, the lowest average value for C is 0.72 which remains higher than the lowest average value for C , i.e. 0.675, obtained at $u'/S_L^0 = 3.67$. One explanation for this decrease may be related to the impact of flame wrinkling. Since the Schlieren technique does not take wrinkles into account, the more wrinkled the flame is, the more differences are expected between the flame contours obtained from tomography and those from Schlieren techniques. As a result, since u'/S_L^0 is assumed from the data to be the parameter with the most impact, an empirical linear correlation is suggested, namely $C = a * \frac{u'}{S_L^0} + b$, where $a = -3.55 \cdot 10^{-2}$ and $b = 0.81$.

Figure 5 – Correction factor C as a function of u'/S_L^0 for all data shaded in Table 1

Future investigations are required to evaluate it for $0 < u'/S_L^0 < 1$ as in laminar conditions the correction factor has to be equal to 1.

In Fig.6a and b, the evolution of $S_{C,Sch}$, the turbulent flame speed obtained from Schlieren radii, corrected by C , is plotted versus the corrected Schlieren radius for different turbulent intensities and different initial pressure conditions, respectively. As highlighted by Wu et al.(Wu *et al.* 2015) and Goulier et al.(Goulier *et al.* 2017), a typical property of turbulent expanding flames is the increase in the flame speed with the radius itself, mainly due to the increase in wrinkling. According to Bradley et al. (Bradley *et al.* 2011b) and Lawes et al. (Lawes *et al.* 2012), the flame can normally only be wrinkled by smaller sized eddies than itself and continues to increase until the flame kernel

encompasses the entire turbulence spectrum. Therefore, the flame speed has to reach a plateau at some point. Unfortunately, due to the size of the windows (70 mm diameter) and of the HIT zone (40 mm diameter) inside the spherical vessel, it is not possible to observe flame radii greater than 20 mm in most cases. However, even for a spherical vessel with a larger diameter, no experimental data obtained by Lawes et al. (Lawes *et al.* 2012), Goulier et al. (Goulier *et al.* 2017), Wu et al. (Wu *et al.* 2015) reached this condition.

Figure 6 –Flame propagation speed versus flame radius for different turbulent intensities (a) ($P_0=0.1$ MPa) and different initial pressures (b) ($u'=1.39$ m/s), obtained from corrected Schlieren data. $T=423$ K, $\Phi = 1.0$.

The increase in the turbulent flame speed due the turbulent intensity and pressure increases is due to the increase in the wrinkling. The effect of pressure for a “low” turbulent intensity is in good agreement with recent data by Lawes et al. (Lawes *et al.* 2012) done at $u'=1$ m/s. In fact, as Galmiche et al. (Galmiche *et al.* 2013) showed, the increase in initial pressure in the vessel induces a decrease in the small turbulent length scales (i.e. Taylor and Kolmogorov ones), especially between 0.1 and 0.5 MPa. After 0.5 MPa, the small length scales cease to evolve for pressures higher than 0.5 MPa, which may explain the absence of effect on the flame speed. Moreover, as the flame thickness decreases with the pressure, the turbulent scale spectrum that can wrinkle the flame towards the small length scales is enlarged, increasing the wrinkles and therefore the flame speed. In fact, it can be seen that the evolution of $S_{C,Sch}$ is similar versus u' , when $u' \geq 1.73$ m/s and versus P_0 , when $P_0 \geq 0.3$ MPa, which corresponds to $u'/S_L^0 > 3$ (cf Table I). As no plateau is reached, there is as yet no consensus

concerning the determination of the turbulent burning velocity (Lawes *et al.* 2012, Wu *et al.* 2015, Goulier *et al.* 2017).

b. Effect of global stretch

Because a propagating flame surface undergoes global curvature, local curvature and flow field strain, the total stretch κ quantifying the turbulence-flame interaction can be separated into 3 terms according to (Chaudhuri *et al.* 2015) :

$$\kappa = \overbrace{\underbrace{S_L \kappa}_{\text{stretch rate by curvature: } \kappa_{c,R}} - \underbrace{(\mathbf{v} \cdot \mathbf{n}) \kappa}_{\text{normal strain rate: } \kappa_n}}^{\text{stretch rate by curvature: } \kappa_\kappa} + \underbrace{\nabla_t \cdot \mathbf{v}_t}_{\text{tangential strain rate: } \kappa_t} \quad (4)$$

This is also similar to the previous work by Candel and Poinso (Candel and Poinso 1990).

The first term represents the stretch due to curvature, $\kappa_{c,R}$, and the second and third ones the stretch rate contributions by the strain rate, κ_s . $\kappa_{c,R}$ is the sum of the stretch rate due to local wrinkling and the strain rate due to the global flame shape. For a spherical propagation, it is calculated as:

$$\kappa_{c,R} = \frac{2}{R_{Sch}} \frac{dR_{Sch}}{dt} \quad (5)$$

As isooctane is more sensitive to stretch than methane (Brequigny, Halter, Mounaïm-Rousselle, *et al.* 2016), the global and local stretches will delay the flame speed increase during propagation (Bradley *et al.* 2011b, Brequigny, Halter, and Mounaïm-Rousselle 2016, Brequigny, Halter, Mounaïm-Rousselle, *et al.* 2016), especially for small radii. In Fig.7, the corrected turbulent flame speed estimated from Schlieren images $S_{c,Sch}$ is plotted versus $\kappa_{c,R}$. As the flame radius during the first part of propagation in the case of spherical propagation is small, it generates strong curvature. This curvature tends to decrease rapidly with the increase in the flame radius. The nonlinear extrapolation of laminar propagation speed evolution, obtained in the same conditions (Endouard *et al.* 2016) is also plotted. From Figure 7, similarities can be observed between the development of turbulent and laminar flame speeds as a function of stretch: first, the flame speed decreases due to the ignition effect, then the flame speed increases as flame stretch decreases and then exceeds the laminar curve especially for $u' > 1.04$ m/s. Moreover after the ignition effects disappear, in the early stage of flame development, the values of flame speed and flame stretch obtained for turbulent cases are comparable to those of the

laminar cases. The main effect of the correction of the Schlieren images is to improve the agreement with the nonlinear laminar extrapolation model. Good agreement was found with Lipatnikov and Chomiak (Lipatnikov and Chomiak 2007), who used Bradley et al.'s data to analyze the effect of global stretch on the burning turbulent velocity. By analogy with the classical Markstein number, they defined a turbulent Markstein number, Ma_t , to characterize the burning turbulent velocity variations, not as a function of the local stretch rate but of the global one. As can be seen in Table 1, Ma_t is in the same order for all conditions. This means that for all turbulent intensities, the flame propagation speed follows globally the laminar development before being impacted by turbulence and exceeding the laminar curve especially for $u' > 1.04$ m/s. By analogy with the laminar speed evolution, U_t^0 , the value of U_t from the interpolation to $\kappa_{c,R} = 0$ can be determined (Lipatnikov and Chomiak 2007, Brequigny, Halter, Mounaïm-Rousselle, *et al.* 2016).

Figure 7– Turbulent flame speed versus the global stretch for different turbulent intensities based on corrected Schlieren data.

Continuous line: nonlinear extrapolation model for laminar propagation in the same initial conditions.

$$P_0=0.1 \text{ MPa}, T=423 \text{ K}, \Phi=1.0.$$

c. Estimate of turbulent burning velocity

As previously discussed, spherical expanding turbulent flames continuously accelerate and an asymptotic value, which corresponds to absolute values of U_t , cannot be determined in the case of most expanding flames. Wu et al. (Wu *et al.* 2015) suggested the following average turbulent burning velocity definition:

$$U_{t,mean} = \frac{\rho_b}{\rho_u} \cdot \frac{3 \int_{R_1}^{R_2} \langle R \rangle^2 \left(\frac{d\langle R \rangle}{dt} \right) d\langle R \rangle}{\langle R_2 \rangle^3 - \langle R_1 \rangle^3} \quad (6)$$

where R_1 and R_2 are 10 and 20 mm, respectively.

From Lipatnikov and Chomiak (Lipatnikov and Chomiak 2007), the extrapolation of the evolution of U_t versus the global stretch at zero stretch should provide a more universal value, $U_t (\kappa_{c,R} = 0)$. In Fig.8 and 9, these different estimates of U_t , normalized by the unstretched laminar flame velocity S_L^0 are plotted versus the usual ratio u'/S_L^0 , for all data conditions at $P_0 = 0.1$ and 0.5 MPa respectively. In (Lawes *et al.* 2012), Lawes et al. choose their last measurable data at $R=30$ mm. The values of Lawes et al. have been added for the conditions closest to those of Table 1. By analogy, the U_t values reached at $R=20$ mm in the present study can also be considered.

First, as expected, the lowest estimate of the turbulent burning velocity is obtained by $U_t (R=20 \text{ mm})$, as the turbulent flame propagation velocity does not reach a plateau at this radius. The estimates of U_t from Eq.6 are the highest ones. Indeed, due to its definition itself, $U_{t,mean}$ is calculated for radii between 10 and 20 mm whereas $U_t (\kappa_{c,R} = 0)$ is obtained from the extrapolation on the longest linear part. The best radius range for the linear extrapolation starts for radius a little bit higher than 4 mm as shown in Fig. 7. Globally a good agreement with the data from Lawes et al. is obtained for $U_t (\kappa_{c,R} = 0)$ at both initial pressures. For comparison, various correlations of turbulent burning velocity are presented in Fig. 8 and 9. First the correlation of (Kobayashi *et al.* 1998), defined in Eq. 7 is introduced.

$$\frac{U_t}{S_L^0} = A_k \left[\left(\frac{P}{P_{ref}} \right) \left(\frac{u'}{S_L^0} \right) \right]^{0.4} \quad (7)$$

with A_k a constant originally set to 1.9.

In Fig. 8 and 9, three other estimates of U_t/S_L^0 were also added:

- the first one (dashed line) suggested by Lawes et al. (Lawes *et al.* 2012) according to the dataset of Bradley et al. (Bradley *et al.* 1992), based on $Ka \cdot Le$ values to take into account the effect of thermal diffusivity/strain.

$$\frac{U_t}{S_L^0} = A_b \cdot \frac{u'}{S_L^0} (KaLe)^{-0.3} \quad (8)$$

with A_b a constant, estimated equal to 0.88 from the dataset of Bradley *et al.*

- the second one (dotted line) suggested by Zimont (Lipatnikov and Chomiak 2002), with the form developed by Driscoll (Driscoll 2008):

$$\frac{U_t}{S_L^0} = 1 + A_z \left(\frac{u'}{S_L^0} \right)^{0.5} Re_T^{0.25} \quad (9)$$

with A_z a constant originally equal to 0.4 as suggested by Lawes *et al.* 2012).

- The last one (dashed dotted line) came from another form of Zimont but by integrating the Lewis Number and Pressure provided by (Muppala *et al.* 2005):

$$\frac{U_t}{S_L^0} = 1 + \frac{A_m}{Le_{eff}} Re_T^{0.25} \left(\frac{u'}{S_L^0} \right)^{0.3} \left(\frac{P}{P_{ref}} \right)^{0.2} \quad (10)$$

with A_m a constant originally equal to 0.46.

It can be noted that the estimates from Eq. 7, 8, and 9 predict higher values than the experiments using the ‘original’ pre-estimated constant values (black lines in Fig.8 and 9). However, the estimates from Eq.10 are in very good agreement with the experimental estimate $U_{t,mean}$ for both initial pressures even with the original constant determined by (Muppala *et al.* 2005). The correlation of Kobayashi *et al.* highly overestimates the 3 experimental estimates of U_t . This can be explained by the fact that the correlation of Kobayashi *et al.* was obtained from the assumption of the development of flame in a fully turbulent regime, which is not the case in the present vessel. According to (Bradley *et al.* 2011a) this happens when the flame radius is higher than 8 times L_T (so higher than 27 mm). One possible way to improve the results would be to use the effective rms turbulent velocity u'_k which correspond to the turbulence actually seen by the flame front, smaller than u' (Bradley *et al.* 2011b, Mannaa *et al.* 2018). The discussion is similar for the overestimate of Eq. (8) which should be computed using u'_k instead of u' . Moreover, the correlation of Kobayashi *et al.* was determined with propane as fuel, so to evaluate it with isooctane implies a modification of the constant A_k and of the exponent factor. The modification of the value of A_k compared with the value of Kobayashi *et al.* is due to the change of the Lewis number when using isooctane instead of propane. Indeed A_k is function of the Lewis

number. In conclusion, the reason for the overestimation of the Kobayashi correlation may be twofold: the fact that the actual turbulence has not been taken into account and the underestimation of the Lewis number effect. Last, the better agreement with $U_{t,mean}$ and trend obtained with the correlation of Muppala et al. could be explained by the fact that its correlation takes into account most of the combustion parameters i.e. the Lewis number, the length scale through the Reynolds, the turbulent intensity, the chemistry through S_L^0 , and the pressure.

Figure 8 – Comparison of various correlations for U_t/S_L^0 as a function of u'/S_L^0 versus experimental data at $P_0=0.1$ MPa (black lines: original correlation, grey lines: adapted correlation).

Figure 9 – Comparison of various correlations for U_t/S_L^0 as a function of u'/S_L^0 versus experimental data at $P_0=0.5$ MPa

(black lines: original correlation, grey lines: adapted correlation).

In order to adapt the predicted estimates to our dataset, the constants A_b, A_z, A_k, A_m in Eq. 7, 8, 9 and 10 were optimized to 0.36, 0.06, 0.95 and 0.2 respectively as done previously (Burke *et al.* 2016). These predicted estimates are plotted in Fig. 8 and 9 in grey. The optimizations were done by minimizing the differences between the predicted and experimental data from this study U_t ($\kappa_{c,R} = 0$) and from Lawes et al. but only by considering $P_0 = 0.1$ MPa data. In order to evaluate the performance of the modified correlations, the mean average absolute differences with the experimental data calculated as follows are summarized in Table 2:

$$\frac{\overline{\Delta U_t}}{U_t} (\%) = \frac{\sum_{i=1}^n \frac{abs(U_{t,correlation} - U_{t,exp}(\kappa_{c,R}=0))}{U_{t,exp}(\kappa_{c,R}=0)}}{n} * 100 \quad (11)$$

Table 2 – Mean absolute percentage difference with the modified correlations described in Eq. 7, 8, 9 and 10 for 0.1 and 0.5 MPa.

P_0 (MPa)	$\left(\frac{\Delta U_t}{U_t}\right)_{Bradley (Eq.8)}$	$\left(\frac{\Delta U_t}{U_t}\right)_{Muppala (Eq.10)}$	$\left(\frac{\Delta U_t}{U_t}\right)_{Zimont (Eq.9)}$	$\left(\frac{\Delta U_t}{U_t}\right)_{Kobayashi (Eq.7)}$
0.1	9.8	14.2	11.1	7.4
0.5	12.1	8.2	20.9	44.0

The optimized estimates from Bradley et al. and Muppala et al. are globally in good agreement even at higher pressure. These two correlations take into account both thermochemical properties (with the Lewis number) and flame turbulence interaction (with either the Karlovitz stretch number or the turbulent Reynolds number). Contrary to what was expected, the effect of pressure on the turbulent burning velocity is not well captured by the ‘optimized’ correlation of Kobayashi et al., even if it based on the pressure effect. Finally, the optimized estimate from Zimont et al. displays quite acceptable values but from Fig. 8 and 9 it appears that this correlation performs less well at high turbulence levels ($u'/S_L^0 > 4$).

Conclusion

In this paper, the empirical correlation between different flame radii (obtained from Mie scattering and Schlieren techniques) suggested by Bradley et al. (Bradley *et al.* 2003) was assessed in order to ensure the validity of the turbulent propagation flame speed estimate from Schlieren images in the case of an iso-octane/air mixture. The correction factor was found to be dependent on turbulence and flame properties, i.e. u'/S_L^0 and displayed values globally in agreement with a more recent study by Bradley et al. (Bradley *et al.* 2011a). However, further work on lower turbulent intensities, higher pressures and dilution rates is still needed to improve this correlation.

The influence of turbulent intensity and pressure was investigated in terms of turbulent flame propagation speed as a function of radius and global stretch to better understand the dynamic of flame propagation. Different estimates of turbulent burning velocities from the experimental data were compared to evaluate their robustness to provide accurate data, comparable to those obtained from different flame configurations to improve model development. Finally, they were compared to estimates from different correlations in the literature to improve the consistency of the experimental data and of these correlations. It was found that the estimates from Muppala et al.'s correlation (Muppala *et al.* 2005) satisfactorily reproduced the experimental values obtained from the definition introduced by Wu et al. (Wu *et al.* 2015). The other correlations overestimated the experimental data from this study and those provided by Lawes et al. In conclusion, the turbulent burning velocity obtained from extrapolation of burning velocity at zero stretch appears to be a good estimate, in good agreement with the 'optimized' estimates from Bradley et al. and the correlation by Muppala et al., where thermochemical properties and turbulence-flame interaction were taken into account.
