Title: RNAi in mice: a promising approach to decipher gene functions in vivo

Biochimie

Dear Dr. Monier,

We are pleased to submit our revised manuscript (BIOCHI-D-05-00188) "RNAi in mice: a promising approach to decipher gene functions in vivo" to Biochimie for publication.

We thank the reviewers for their valuable comments and have revised the manuscript accordingly (all the changes are marked with bold face). We hope that the revised manuscript will be suitable for publication in Biochimie.

Responses to Reviewer #1,

- *The minor point has been corrected (showing)*

Responses to the Editorial Board

- *Figures are now provided in tiff files.*

Best regards,

Abstract

RNA interference (RNAi) is a simple and powerful tool widely used **to study** gene functions in many species. Vector-based systems using RNA polymerase III promoters have been developed to achieve stable expression of small interfering RNA (siRNA) or small hairpin RNA (shRNA) in mammalian cells. Recent investigations demonstrated that **when, combined** with the Cre-loxP system, the vector based RNAi can be used to achieve conditional or tissue specific knockdown of endogenous genes with high efficiency in mice. Here, we review these recent progresses and discuss the advantages, limitations and future development of **this emerging** technology.

Keywords: RNAi, mice, knockdown, Cre-loxP, Fgfr2

Introduction

Since the publication of the first transgenic mice in 1980 [1], mouse genetics constitutes one of the primary fields to explore the consequence of manipulating gene expression. The transgenic approach and gene targeting (knockout) in mice make possible to modify any genes with **various mutations**, i.e. over expression, constitutive activation, loss of function, hypomorphic mutation, conditional and/or tissue specific inactivation [2-5]. Despite great efforts have been made to improve efficiency of these techniques, the manipulation of genes remains difficult and time-consuming. For example, the generation of a knockout or conditional knockout mouse requires years of work and sometimes does not yield to significant results. This accounts for one of the main reasons why the published knockouts represent only 10% of mouse genes of 30,000 [6]. On the other hand, generation of transgenic mice remains the quickest way to obtain results on the function of a specific gene, **although it primarily** gives information from over-expression. Recently, many laboratories **have developed various methods to knockdown gene expression using RNAi in mice**. In this review, we will mainly discuss these recent progresses. Readers who are interesting in any other aspects of RNAi are referred to a number of other recent reviews [7-10].

How RNAi works?

RNA interference corresponds to a specific target mRNA degradation involving small perfectly homologous double-strand RNAs also called small interfering RNAs (siRNAs). This leads to a decrease (but not absence) of expression of the corresponding protein. This natural process has been discovered in 1998 in the invertebrate nematode *Caenorhabditis elegans* [11, 12]. Other studies have shown that RNAi is a common process encountered in unicellular protozoa's, insects, fungi, but also plants and vertebrates [13]. Originally, RNAi has probably evolved to fight against viruses and transposable elements that include a double **strand** RNA step in their replication cycle [14]. It is also generally assumed that RNAi is involved in developmental **processes** in multicellular organisms and chromatin structure regulation [15, 16].

Basically, when a double **strand** RNA or an RNA containing an equivalent structure (generally due to homologous folding) is introduced or produced in a cell, **a ribonuclease called Dicer recognizes this molecule and processes it into** short double **strand** RNA of 21-base pairs (bp) containing 2-nucleotide 3'-overhangs. These molecules, called siRNAs, can also be easily introduced in any cells during transient transfection experiments. A multi-subunit complex called RISC (RNA-induced silencing complex) then binds **one molecule of** siRNAs (**Fig. 1**). Among its subunits, a helicase unwinds the siRNA and one of the strands is used as bait by a homology-searching component to catch an endogenous target mRNA bearing the same sequence. Upon binding, the mRNA is degraded by the RISC endonuclease and exonuclease subunits; a new cycle then begins. Thus, any mRNA bearing a homologous sequence with a siRNA is degraded **and its expression is knocked down to 10-40 % of its normal levels** [17].

In addition to this linear mechanism, plants, worms and insects have developed an amplification loop with an additional enzyme complex called RdRp for RNA-dependent RNA polymerase [18]. The siRNA provides sequence-specific primers and the target mRNA is used as the template. The RdRp complex produces large quantities of siRNAs and then an additional defense mechanism. This alternate step does not exist in mammals [19-21].

RNA interference techniques have become widely used in numerous laboratories since Elbashir and al [22-24] first described efficient knockdown in transfected mammalian cells with in vitro **synthesized siRNAs**. Their size needs to be <22 base pairs. Longer siRNAs activate **an interferon reaction, leading to a general inhibition of translation, rather than the desired specific knockdown** [22-24]. However, an increasing number of publications using microarrays suggest that short siRNAs (<22 bp) might also induce non-specific knockdown [25-27]. On the other hand, a few studies demonstrated a very specific effect of one siRNA on a large scale [28-30]. One evoked reason for an eventual non-specific effect is a special interferon response for short siRNA [25, 27]. Another reason might be the huge quantity of small dsRNA that are transfected in each single cell. The development of sh (small hairpin) RNA-synthesizing vectors has allowed a better control of in vitro RNA interference. Indeed, several laboratories have developed new plasmids **containing polymerase III promoters**, like the ones of the U6 and H1 genes, known to synthesize small RNA. Those vectors allow synthesis of 50 bp-long single strand RNA that folded in 21-23 bp dsRNA with a small hairpin in the middle. These shRNAs lack a 5' cap and a long polyadenylated tail [31-33].

Alternatively, other vectors have been created that allow synthesis of two complementary short RNA duplexes forming then a siRNA [34, 35].

These constructs have several advantages. First, they allow a smoother synthesis of shRNAs in the cell compared to the brutal transfection of numerous siRNA molecules. Secondly, the time of action of **a shRNA lasts much longer than a siRNA does, as the shRNA vectors can be stably integrated into the genome of recipient cells** [36]. Finally, expression of these vectors can be controlled by inducible elements to achieve temporal and spatial knockdown of genes of **interest**, which will be discussed further in this review.

RNAi in mice

RNA interference can be performed at the whole animal level. *C. elegans* and *Drosophila* can be easily manipulated by soaking the animals in a solution containing siRNAs or by adding bacteria expressing siRNAs to the diet [37, 38]. **Significant and quick knockdown (72 hours after soaking) can be obtained with these procedures; however, they cannot be applied for mammals.**

RNAi mediated gene knockdown in mice has been **performed throughout various techniques at multiple levels**. siRNAs or long dsRNAs (>500 bp) synthesized by an oocyte-specific promoter (from a vector) have been injected into mouse oocytes and zygotes to study gene functions during embryonic development [21, 39]. **The injected oocytes or embryos can be maintained in culture condition in a specific medium and their phenotypes and growth properties can be monitored.** These studies showed that efficient knockdown of transgenic eGFP, endogenous c-Mos or E-Cadherin could be achieved. We have mentioned **earlier** that long dsRNA might

generated a non-specific response due to their length; however, it appears that, in oocytes, they do not activate the same pathways previously described in somatic cells. Thus, this technique looks suitable to study early development of the embryos.

Taken advantage of the dominant nature of the RNAi, **embryonic stem (ES)** cells carrying stably integrated shRNAi **vectors** were also used to **generate embryos** by tetraploid aggregation method [40, 41]. **Because the tetraploid embryos can only form the placenta and the yolk sac in the fusion embryos owing to their increased ploidy, the entire embryo proper is ES cells derived. In one of the study, the authors showed that strong expression of an shRNA targeting RasGAP, a p120-RAS GTPase-activating protein, impaired normal development at embryonic day 9.5. Severity of the phenotype was concordant with the levels of shRNA knockdown [40].** The delivery has also been improved by the use of various adeno-, lenti- or retrovirus **to increase transfection efficiency** [42, 43]. All those experiments have shown efficient knockdown of exogenous or endogenous genes like p53, Bim, CD25 or CD8 α . Additionally, Hemann and co-workers introduced hematopoietic stem cells expressing p53-targeting shRNA into irradiated mice and observed several kinds of phenotypes in reconstituted organs, which were correlated with the shRNA expression levels [44]. All those experiments show that RNAi could be performed in mice at the cellular or embryonic level.

To target an adult mice, shRNAs or siRNAs has been administrated using a method called “tail vein injection” (or “hydrodynamic transfection method”), which had been widely used before to allow expression of a variety of plasmids in the liver [45-47]. **Basically, a solution of DNA (ranging from 10-500 μ g desolved in 2.5 mL of Ringer’s**

solutions) is injected into recipient mice through tail vein with a 27-gauge needle. The levels of transgene expression depend on the volume and injection rate. Under slow conditions of injection, the DNA enters the blood stream and is rapidly degraded by the blood nucleases. The “high-pressure” delivery leads to the accumulation of the DNA solution in the inferior vena cava; indeed the injected volume is almost equal to the blood volume and the cardiac output is overflowed by the rapid delivery of the DNA solution. The resulting high pressure surrounding the liver allows the “DNA transfection” into the parenchyma. Toxicity studies show that most animals recover well from the procedure [45]. Expression of a gene coding by the DNA can be observed within the first 24 hours and approximately 50% of hepatocytes express the transgene [45, 47]. In addition, several laboratories have shown that it was also possible to deliver naked plasmid DNA to various tissues (i.e. muscle and liver) through direct injection into the tissue or into the vessels surrounding the organ (portal vein, hepatic vein or bile duct for the liver) [47].

Lewis *et al* (2002) were the first to knockdown transgenic eGFP expression using RNAi in mice **using the hydrodynamic transfection method** [48]. Human viral RNAs (Hepatitis B and C) have also been targeted by other laboratories using the same procedure [49-51]. More recently, Song and colleagues performed a similar experiment on the Fas gene, a protein sometimes involved in autoimmune hepatic diseases, and protected the mice against fulminant hepatitis [52]. Those experiments have shown that the liver could be easily targeted to disrupt functions of exogenous, **or** endogenous genes. Unfortunately, this could be obtained mainly in the liver and only for a short period of time (**around 1 week**). **Repeated** injections must be performed to reach an efficient

knockdown effect [48]. The use of cationic liposome has shown that it was possible to target other organs in addition to the liver with a GFP-based RNAi experiment [53]. **The protocol is closed to the ones used commonly for transient transfection experiments at the cell culture level: a cationic lipid is complexed with siRNA and plasmid DNA coding the target mRNA. Equivalent knockdown of eGFP expression in the liver and the spleen was observed 72h after intravenous administration of the siRNA specific to eGFP. In the same study, the authors also demonstrated that the intraperitoneal injected siRNA specific for TNF α favored development of sepsis in liposaccharide-treated mice [53].**

Most notably, Hasuwa and colleagues (2002) used a transgenic approach by directly injecting an shRNA construct against eGFP to the pronucleus of zygotes [54]. The transgenic mice were then crossed with mice that ubiquitously express the eGFP gene. Their data demonstrated that expression of the eGFP siRNA efficiently silenced the eGFP gene in every part of the mouse analyzed. This study proves in principle that shRNA can knockdown genes in mice.

Inducible RNAi in mice

Our review of literature thus far has revealed the feasibility of RNAi-mediated gene knockdown in mice with high efficiency. However, with a threat of knockdown-induced lethality, new strategies have taken in account the possibility to generate inducible or tissue restricted models. These models in theory can bypass embryonic lethality and allow the study of specific genes in specific tissues. Several approaches have been developed in cultured cells, including tetracycline-inducible shRNA, ecdysone-

responsive system, and tamoxifen-induced Cre/loxP recombination system [30, 32, 55-59].

Although all these approaches are promising, so far only Cre/loxP mediated RNAi has been reported to knockdown endogenous genes in mice. Two studies used lentivirus based RNAi systems, in which shRNA expression is controlled by a lox-stop-lox element. Because the stopper is placed between the TATA-box and the transcription start site of the U6 promoter, the **shRNA** cannot be expressed until it (**lox-stop-lox element**) is deleted by Cre-mediated excision [60, 61]. The third study by our group used a plasmid-based strategy [32, 33]. Our data demonstrated that the plasmid-based RNAi system is both simple and easy to use, and works with high **efficiency** in silencing expression of endogenous genes.

In this approach, a neomycin cassette was inserted in the U6 RNA polymerase III promoter to disrupt its activity. **The *neo* gene not only functions as a stopper but also serves as a selection marker when the shRNA construct is used in cell culture system.** The neomycin cassette is flanked by loxP sites and can be deleted through the Cre/loxP mediated recombination [5]. After checking the efficiency of the system at the tissue culture level on two endogenous genes, *Fgfr2* and Survivin, we found that the U6 activity can be completely restored upon the excision of the *neo* by Cre/loxP mediated recombination [32]. We then decided to generate mice bearing our *Fgfr2*-targeting construct (*U6-ploxPneo-Fgfr2*) to test its *in vivo* efficiency. FGFR2 is one of the four high affinity FGF receptors that mediate the signaling of, at least, 22 FGF ligands [62]. In humans, missense mutations of FGFR2 have been related to **craniosynostosis** and limb abnormalities [62]. *Fgfr2* also plays an important role in embryonic development and

organogenesis [62]. Consistent with our *in vitro* study [showing](#) that the presence of the *neo* inhibits the U6 promoter activity, transgenic mice bearing the *U6-ploxPneo-Fgfr2* shRNA **construct** showed no abnormalities. When crossed with *Ella-Cre* transgenic mice, which express Cre in the mouse germline [63], *ploxPneo* is excised leading to activation of the U6 promoter and FGFR2-shRNA synthesis (Fig. 2A,B). We next determined levels of *Fgfr2* expression by RT-PCR and found that all *U6-Fgfr2;Ella-Cre* embryos exhibited dramatically reduced **Fgfr2 transcripts** while no obvious alteration was observed in all control embryos (Fig. 2C). Our analysis also revealed that *U6-Fgfr2* RNAi-mediated suppression is specific to *Fgfr2* but not **to** any other family members (Fig. 2C). Next, we performed realtime-PCR analysis and were able to confirm dramatic downregulation of *Fgfr2* transcripts in the *U6-Fgfr2;Ella-Cre*, but not in any other control embryos (Fig. 3B).

Previous studies showed that *Fgfr2* mutant embryos generated by gene targeting died during embryonic stages [64-66]. Consistently, we found that a majority **of** *U6-Fgfr2;Ella-Cre* embryos died at middle gestation (Fig. 3A). On the other hand, when crossed with a transgenic strain that expresses Cre in the progress zone of the limb [67], embryos reach birth but with associated limbs and digits abnormalities (Fig. 3B), demonstrating in principle that the combination of the Cre/loxP and RNAi approaches can be used to decipher gene function in a tissue specific manner.

Advantages, limitations, and perspectives

Most RNAi experiments performed in mice have been compared with counterpart recombination knockout studies and most of them have revealed similar phenotypes [21, 33, 39, 40, 60, 61]. **However**, RNAi knockdown in mice may have several advantages.

Currently, knockouts studies represent only 10% of total mouse genes [6]. Generation of **transgenic** mice carrying RNAi construct is fast; in our hands, we were able to produce several pure carriers in only 3 months (the time schedule to produce regular transgenic mice) compared to 12-24 months for conditional gene knockouts. Moreover, because RNAi acts dominantly, only one allele of transgene is needed to suppress the endogenous target gene, it reduces the time needed for breeding together two mutant alleles required by conditional knockout of genes with recessive nature. This advantage becomes more obvious when genetic interaction of two or more genes is studied [64, 68]. Thus, compared with the gene targeting technique, RNAi approach is both fast and simple, and therefore should be widely accessible. In this aspect, the existence of a large collection of Cre transgenic lines (<http://www.mshri.on.ca/nagy/cre-pub.html>) should make it possible to have a quick assessment of RNAi-mediated gene knockdown in the tissue specific fashion.

On the other hand, RNAi-mediated gene knockdown cannot replace gene targeting because expression of endogenous genes is not completely repressed. Instead, it should be used as a complement approach to study functions of genes, especially to those whose absence results in embryonic or early postnatal lethality. Generation of mice carrying mild phenotypes or various hypomorphic alleles could greatly facilitate studies in many fields of biological sciences. For example, knockout DNMT1 is lethal but only 10% expression is enough for a mouse to survive. On the other hand, those mice have a clear phenotype, given information on the gene function [69]. Such level of down-regulation is clearly in the range of an RNAi experiment.

Those advantages must not hide the limits of this new technique: among them, insertion of transgenes is still a matter of random in the genome. Then, the RNAi construct will always be dependant of the so-called positional variegation [70]. It was recently reported that the position effect could be minimized or overcome using an insulator [71]. Alternatively, RNAi construct can be targeted in the ES cells to a site that allow ubiquitous expression of the exogenous genes, such as Rosa-26 locus [72]. **In addition**, non-specific knockdown might be the biggest challenge for RNAi in vivo experiments. This problem might be solved by a careful selection of the RNAi sequences. **Target structure, base composition and internal thermodynamic stability are important parameters to design a siRNA. The design of the siRNA or shRNA remains crucial and carefully accomplished [73].** Useful web sites for the design of effective si/shRNAs can be found in a recent review [74]. Using different shRNA or siRNA targeting the same gene has also been suggested to overcome this problem [44]. **Finally, creating a transgenic line, although faster than the knockout strategy, is still time consuming. It is still appropriate to first assess the efficiency of the construct or the siRNA in transient transfection experiment in cell culture. New approaches for mammalian systems might have also been developed that used type II promoters and RNA polymerase II; two recent papers mentioned such techniques that appear to be more effective than the now traditional shRNA option and that could also be tightly regulated [75, 76].**

Because shRNA constructs can be injected into the pronucleus of fertilized eggs, it can be applied to many other species where ES cells have not been established. A successful example has been reported in rat [54]. With the continuous increased

efficiency RNA interference and improved delivery in vivo, it is conceivable to imagine new human therapeutics involving controllable RNAi constructs to knockdown expression of alleles carrying missense mutations commonly seen in numerous forms of genetic diseases, such as those occurred in FGF receptors [62, 77].
