Identification of the state of suspension elements in railway systems

The running safety and passenger comfort levels in a vehicle are tightly related to the technical state of the suspension elements. The technical state of the suspension depends of the service life time as its components become old and wear out. A study on the dynamic behavior of a railway vehicle is established in relation to the damping elements in one of its suspension stages. An experimental measurement model is developed, obtaining a set of useful signals for the identification of the dynamic parameters of the vehicle and developing a test through the application of the OMA technique, using LSCE method as a basis to validate the numeric model of the multi-body system. Then, the study focuses on developing numeric simulations for the identification of the technical state of the dampers by the registration of dynamic variables under commercial service conditions and on estimating the state of the suspension elements.

Keywords: IRF, LSCE, multi-body model, OMA, railway testing, stabilization diagram.

1. Introduction

The modal properties of a dynamic system are traditionally obtained using techniques known as Experimental Modal Analysis (EMA). EMA techniques have been widely documented [1–3], nonetheless, for many cases relative to civil and mechanical structures it is difficult to apply the excitation with an impact hammer, shaker, etc. due to the size, shape, fragility or location [4].

For systems with auto-motion (aircraft, automobile, ship, train, etc.) it is necessary to know the modal parameters under normal running conditions, considering the particular characteristics of: boundary condition, distribution of forces in the frequency domain and level of response [5]; these systems possess normal operating condition which are difficult to reproduce in a laboratory, for which it is necessary to measure the physical and modal parameters during the operation.

The Operational Modal Analysis technique (OMA) is only based on the measurement of the response signals and uses the environmental excitations as non-measured signals [6]. OMA is used for the modal identification with high precision

under typical operating conditions [7]. The following are some of OMA main advantages:

- It is possible to submit to this test systems whose excitation through the application of artificial external forces do not allow to obtain correct measurements; there are mechanic systems (e.g. freight train, suburban train, tramway) for which the sources of excitation (creepage phenomenon in the contact patch on the wheel-rail interface) can not be measured individually in a precise way, and as a result an erroneous modal model is obtained [8]. The only parameters that can be measured in an exact way are the response data [9].
- In situ tests can be developed without interruption and in parallel with other applications. It is not necessary to move the system to a laboratory to realize the tests under controlled conditions. In situ tests avoid the need of having an express test bank [10]. In consequence, it avoids the system to be submitted to inactive time.
- It is a simple test procedure similar to the Operating Deflection Shapes (ODS) technique, which employs a reference transducer and various mobile response transducers. OMA does not use reference transducers in the case where all the responses are measured synchronously; on the other case, one or some transducers are used depending on the number of repeated roots that are obtained. Any of the measurements can be employed as reference, which means that OMA is a Multiple-Input Multiple-Output (MIMO) technique and allows to estimate very proximal modes with high precision [8, 10].

2
3 A technique (see Figure 1(a)) has been adopted for the evaluation of the
4 technical state of the dampers through the measurement of variables under operating
5 conditions of the vehicle using the OMA-LSCE method, this meaning with the
6 excitations of the operating conditions which originate from uncontrolled sources.
7
8 The present work exposes the steps to be followed in order to identify the technical
9 state of the suspension elements.

18 Using the properties upon which the natural excitation technique [11] is based,
19 the response functions of random noise can be used to determine the Impulse
20 Response Function (IRF). The modal parameters of the system can be identified using
21 standard identification methods in time domain [10]. In this paper the Least-Squares
22 Complex Exponential method (LSCE) will be used.

31 LSCE is an OMA method in time domain whose procedure is illustrated in
32 Figure 1(b). LSCE method determines the relation between the IRF in a Multiple
33 Degrees of Freedom (MDoF) system, its complex poles and residues through a
34 complex exponential. The IRF can be derived from the inverse Fourier transform (FT)
35 for a Frequency Response Function (FRF) through the Random Decrement process
36 (RD), or other methods. An Auto-Regressive model (AR) is constructed by the
37 relation between poles and residues; the AR model solution allows to define a
38 polynomial in whose roots are the complex roots of the system. Having established
39 the roots (equivalent to the natural frequencies Ω and the damping rates ξ), the
40 residues can be derived through the AR model and then obtain the modal shapes ϕ

The inverse Laplace transform of the transfer function of a MDoF system is the IRF, h_k . This gives as a result a series of equally spaced time intervals $k\Delta$ ($k = 0, 1, \dots, 2N$), then it is possible to express IRF as

$$h_k = \sum_{r=1}^{2N} r^{k-1} \sum_{i=1}^n [(r^*)^i] A_{ij} z_r^k, \quad z_r^k = e^{s_r k \Delta},$$
 where

$$[(r^*)^i] A_{ij} = [\phi]_i^T r^* [\phi]_j^T.$$

This expression is the product of the i th and j th elements in the modal shape r th $(\phi)_r$ and is named as the *modal constant*. The values in the series belong to the real numbers even if the residues and the roots s_r are complex values. It is possible to demonstrate that all imaginary parts will cancel each other because of the complex conjugates for both expressions: $(r^*)^i] A_{ij}$ and s_r . The next step is to estimate the roots and the residues for the sampled data. This solution is aided by the conjugacy of the roots s_r , therefore z_r . Mathematically, this means that z_r are the roots of a polynomial with only real coefficients [4]

$$\beta_0 + \beta_1 z_r + \beta_2 z_r^2 + \dots + \beta_{2N-1} z_r^{2N-1} + \beta_{2N} z_r^{2N} = 0,$$

or

$$\sum_{k=0}^{2N} h_k = 0 \Rightarrow \sum_{k=0}^{2N} [\beta_1 h_k - h_k] = 0 \Rightarrow \sum_{k=0}^{2N} r^{k-1} \sum_{i=1}^n [(r^*)^i] A_{ij} \sum_{k=0}^{2N} z_r^k = 0 \Rightarrow \sum_{k=0}^{2N} z_r^k = 0.$$

This equation is known as the Prony equation. The coefficients can be estimated by the IRF values.

With the calculation of the system poles, it is possible to build the stabilization diagram, which allows to graphically represent the poles of a system when it is excited in one point (reference) and measurements are made in another one (responses) [12]. The poles are codified with alphanumeric characters: stable pole (s), vibration frequency and modal vector are stable (v), vibration frequency and stifling are stable (d), only stable the vibration frequency (f), and unstable pole (o). Once the poles have been selected it is possible to estimate the vibration shapes [13].

{Figure 1}

2. Description of the object of study

The study is applied to passengers' vehicles belonging to the massive transport railway vehicle fleet of Medellin city (Colombia), which is a railway system similar to suburban trains. Original equipment manufacturer of rolling stock was MAN for mechanical components and Siemens for electrical components. MAN has since become Adtranz company and subsequently Bombardier Transportation. The vehicles are similar in geometry and design to the ET420 train sets formerly operated by Deutsche Bahn in commuter service (e.g. the Munich S-Bahn) [4, 14].

The railway system has 42 three-unit cars (see Figure 2(a)). Each car has two (2) bogies that are supported over two (2) axle-wheel sets. Each car has a suspension of two (2) stages: primary and secondary [14, 15].

The primary suspension stage is composed by elastic and damping elements that connect the axle-wheel to the bogie (helicoidal springs, guide leafs and vertical dampers); the secondary suspension stage connects the bogie to the carbody (pneumatic spring, traction link, vertical and transversal dampers).

The end cars are powered, while the center unit is an unpowered trailer car. The end cars bogies have a DC motor located in transversal position, partially suspended over the axle and over an elastic suspension connected to the bogie frame, there is one 205 kW motor per axle [14, 16].

An EMA technique [4] has been used to determine the behavior of the vehicle under a given operating condition. EMA technique is applied to a set of tests based on the excitation and the response measurement of the vehicle, according to the theory on

the classic modal analysis. The excitation of the vehicle is achieved by a manual inputs applied directly to the carbody, in the location and direction necessary to induce a specific shape mode. In order to be able to generate the excitation it is necessary to remove the damping elements of the vehicle suspension, condition denominated ϵ_0 that allows the carbody to be excited by hand.

To obtain a better capture of the signals in the transducers (accelerometers) [17], these have been located at the ends of the carbody, collinear to the longitudinal plane of the carbody. The data is realized with a minimum sample frequency of 50Hz [13].

The set of recorded signals is transformed to the frequency domain through FFT algorithm to obtain the characteristic frequencies of the carbody, finding the corresponding modal shape [4, 18, 19]. Table 1 shows the results obtained from EMA technique.

This work focuses on the study of the vehicle dynamic response [11], which is influenced by the technical state of the four (4) identical vertical dampers that each car has, δ_j with $j = 1, \dots, 4$ (see Figure 2 (b)). This type of component is characterized by a set of physical laboratory tests. The test's method requires the application of cyclical displacement excitation (sinusoidal) in determined ranges of frequency and peak-to-peak amplitudes [4, 15, 19]. The relation obtained from the characterization of the element is denominated *nominal damping function*, ϵ_{10} . From ϵ_{10} , a set of nine (9) hypothetical properties are established, ϵ_i with $i = 1, \dots, 9$. The hypothetical properties have a similar behavior to ϵ_{10} , but affected by a coefficient that reduces de damping property of the element δ_j , $\epsilon_i = \frac{i}{10} \epsilon_{10}$. This is how the different technical

states of the component are represented, causing a progressive degradation of the *damping function*. (Figure 2(c)).

{ Figure 2 }

{ Table 1 }

Three (3) hypotheses are established in relation to the state of the suspension elements δ_j , which is defined parametrically by the progressive degradation of the *damping function*:

- Hypothesis ζ_1 : consists on the reduction of the damping function, varying the technical state ϵ_i of the four (4) secondary vertical hydraulic dampers δ_j , with $j = 1, \dots, 4$.
- Hypothesis ζ_2 : consists on the reduction of the damping function by varying the technical state ϵ_i of the two (2) leading dampers (δ_1, δ_2), these being the ones located at the closest distance to the driver; the other two (2) dampers (δ_3, δ_4) conserve the nominal property ϵ_{10} .
- Hypothesis ζ_3 : consist on the reduction of the damping function by varying the technical state ϵ_i of the two (2) training dampers, these being the ones located at the end opposite to the driver (δ_3, δ_4); the other two (2) dampers (δ_1, δ_2) conserve the nominal property ϵ_{10} .

3. Development of numeric models

A model of the railway vehicle can be developed and put in motion on a typical track and instrumented in a virtual environment, which allows investigating the effects of a wide range of possible variations of the vehicle parameters [4, 11]. The results

obtained from a model can provide accurate predictions of the dynamic behavior of the vehicle and the interaction with the track [20 – 22].

The general approach of a virtual model is to numerically integrate the ordinary differential equation that constitutes the model by using one or various integration algorithms. This approach is usually denominated simulation or numerical experimentation, which is equivalent to physical experimentation where the system is subject to given conditions and its response is registered. This approach is convenient because it [3]:

- allows to different types of models and complexity degree; and
- evaluating the response of any type of perturbation.

But it has limitations such as [3]:

- does not allow identifying the whole behavior of the system, only the response under defined conditions;
- requires computing resources. It generates high computational costs in cases where the system is complex or the model has characteristics that make the numeric integration a difficult procedure; and
- allows the variation effects of the parameters to be predicted, only with a high quantity of simulations.

The numeric model used to simulate the characteristics of the system is considered to be a true virtual prototype. The virtual techniques allow the model to generate information on the dynamic behavior and the interaction of the components, which are only comparable to physical prototypes. Simulations with numeric models are a valid source of the necessary data to apply the formulated methodology. The

virtual techniques allow the model to generate a great quantity of information not only on response and dynamic behavior, but also relative to the interaction of the components, load details and even aesthetic qualities that are only comparable to physical prototypes [4, 11, 12, 21].

The numeric model developed has 120 DoF [15], the model consist of the union of two (2) simplified models (see Figure 3(a)) and represents a complete motor car (see Figure 3(b)). It is based on the multi-body system theory, using the analysis software VAMPIRE® [23]; the values of the particular parameters of the model are exposed in Appendix 2.

{Figure 3}

4. Test development in a virtual environment

It is necessary to point out the guidelines for the correct development of the test. The coherent design of the experiment allows a correct analysis of the data and it must be designed to evaluate the secondary suspension under normal operating and controlled conditions, without affecting the operation and the security of the system. The test is defined following these conditions:

- the necessary load condition (AW0), this meaning that the car is empty;
- the section track is straight track and the track irregularities are considered [24];
- the vehicle speed, $V=80\text{km/h}$; and
- a variation of the secondary suspension dampers technical state is assumed ϵi (see Figure 2 (c)).

The measurement points are defined according to the railway international standards [25]. Given that the interest of this work focuses on the study of the secondary stage vertical suspension, the signals to be recorded must in the main bodies of the system, in this way three (3) signals in vertical direction are chosen. The signals are located in:

- $\bar{z}_{q1}^*$, on the floor of the carbody, at leader side (**Error! Reference source not found.**(a));
- $\bar{z}_{q1}^+$, in the bogie frame near to the attack axle (Figure 4(b)); and
- $\bar{z}_{q1}^o$, in the axlebox of the attack axle (**Error! Reference source not found.**(c)).

{Figure 4}

5. Processing and results with the OMA-LSCE method

The set of signals $\bar{z}_{q1}^*$, $\bar{z}_{q1}^+$, and $\bar{z}_{q1}^o$ is processed by the OMA-LSCE method, based on the measurement of response of the system to the excitations of the operation and from which the global modal parameters are estimated: Ω , ξ and ϕ [12]. The modal parameters are graphically represented by the stabilization diagrams. Appendix 3 exposes as an example a set of stabilization diagrams obtained from different operating conditions of the vehicle. In the diagrams it is possible to identify:

- two (2) local maximums in the range [1, 2.5]Hz, which correspond to the two (2) modal shapes (bounce ϕ_2 , and pitch ϕ_1) and are registered in the carbody by the sensor $\bar{z}_{q1}^*$;

- three (3) local maximums in the range [4, 10]Hz, which correspond to the three (3) modal shapes recorded from the bogie by the sensor $\ddot{z}_{q1}^*$; and
- three (3) local maximums in the range [15, 25]Hz, which correspond to the vertical irregularities of the track and are obtained from the signal registered by sensor $\ddot{z}_{q1}^o$.

The work focuses on the analysis of the vehicle, more specifically in the carbody for which it has been possible to identify two (2) vertical modal shapes (ϕ_2 , ϕ_4) under the load condition AW0, see Table 2.

{Table 2}

6. Analysis of the results

From the set of values of the modal parameters identified for the different hypothesis ζ_i it is possible to show the existing relationship between the technical state of the damping set and:

- the natural frequency Ω , of the modal shape ϕ_2 y ϕ_4 , obtaining regressive lineal models with a correlation coefficient value of $\sqrt{R^2} > 0.98$ (see Figure 5); and
- the damping rate ξ , obtaining regressive exponential models with correlation coefficient values of $\sqrt{R^2} > 0.96$ (see Figure 6).

The regressive models are considered valid given that the values $\sqrt{R^2}$ represent an association measurement of the statistical model with the obtained data [26], which have an acceptable level for the reach of this work.

{Figure 5}

{Figure 6}

7. Validation of the test

The regressive models belonging to ζ_1 and obtained by OMA-LSCE in a virtual environment are extrapolated to the value of the technical state of the damper with a null *damping function*, ϵ_0 , for the modal shapes ϕ_i , meaning:

for ϕ_2 ,
 $\epsilon(\omega) = 9.577 \left(\omega - 13.950 \right) \Delta \omega$ "if" $\epsilon = \epsilon_0 \rightarrow \omega = 1.46\text{Hz}$, and
for ϕ_4 , $\epsilon(\omega) = 8.761 \left(\omega - 18.326 \right) \Delta \omega$ "if" $\epsilon = \epsilon_0 \rightarrow \omega = 2.09\text{Hz}$.

In this way the dynamic behavior of the vehicle without the secondary damper is obtained, emulating the whole extraction of the damping elements of the suspension δ_j with $j = 1, \dots, 4$; which is the same testing condition realized to the vehicle with the EMA technique.

The values reordered by the two (2) types of analysis, EMA and OMA, are compared (see Table 2) which allows observing that there is an estimation error of the modal parameter, $(\% < 1\%)$. Therefore, it is possible to consider valid the regressive models given that the ϵ values represent an acceptable deviation level for the reach of this work.

{Table 3}

8. Case study, application of the regressive models

Given the set of signals, $\ddot{z}_{q1}^+$, $\ddot{z}_{q1}^-$, y $\ddot{z}_{q1}^0$, obtained from a car. The data has been processed through OMA-LSCE, the following identification of modal parameters is obtained:

- natural frequency: $\Omega = 1.53$ Hz for ϕ_2 , and $\Omega = 2.18$ Hz for ϕ_4 ; and
- damping rate: $\xi = 2.90$ % for ϕ_2 , and $\xi = 2.20$ % for ϕ_4 .

Starting from the identified modal parameters and based on the series of regressive models obtained for the vehicle, the probable state of the damper is identified ϵ_i , for each one of the hypothesis ζ_i . The regressive models in the identification of the modal shape ϕ_2 are:

$$\begin{aligned} \text{for } \zeta_1, \epsilon(0) &= 9.577 \left(1 - 13.950 \cdot e^{-1.53 \cdot \xi} \right) = 0.70, \\ \epsilon(\xi) &= 0.084e^{0.733\xi} \quad \therefore \epsilon(2.90) = 0.70, \\ \text{for } \zeta_2, \epsilon(0) &= 13.161 \left(1 - 19.567 \cdot e^{-1.53 \cdot \xi} \right) = 0.57, \\ \epsilon(\xi) &= 0.027e^{1.056\xi} \quad \therefore \epsilon(2.90) = 0.58, \\ \text{for } \zeta_3, \epsilon(0) &= 13.958 \left(1 - 20.873 \cdot e^{-1.53 \cdot \xi} \right) = 0.48; \\ \epsilon(\xi) &= 0.008e^{1.365\xi} \quad \therefore \epsilon(2.90) = 0.42; \end{aligned}$$

in the modal shape ϕ_4 are:

$$\begin{aligned} \text{for } \zeta_1, \epsilon(0) &= 8.761 \left(1 - 18.326 \cdot e^{-2.18 \cdot \xi} \right) = 0.77, \\ \epsilon(\xi) &= 7.207E-5e^{4.151\xi} \quad \therefore \epsilon(2.20) = 0.67, \\ \text{for } \zeta_2, \epsilon(0) &= 23.326 \left(1 - 50.240 \cdot e^{-2.18 \cdot \xi} \right) = 0.61, \\ \epsilon(\xi) &= 1.855E-4e^{3.773\xi} \quad \therefore \epsilon(2.20) = 0.75, \\ \text{for } \zeta_3, \epsilon(0) &= 25.431 \left(1 - 54.825 \cdot e^{-2.18 \cdot \xi} \right) = 0.61; \\ \epsilon(\xi) &= 5.334E-4e^{3.279\xi} \quad \therefore \epsilon(2.20) = 0.72. \end{aligned}$$

The ϵ values from the hypothesis ζ_i are tabulated (Table 4). The mean of the technical state is calculated, $\bar{X}_i$ as well as their corresponding standard deviation σ_i , the later will be the criteria that defines the valid hypothesis ζ_i . The ζ_i that presents the least standard deviation is the one that adapts to the obtained dynamic characteristics of the system and therefore the value $\bar{X}_i$ of such hypothesis must be the technical state of the damper ϵ , meaning $\zeta_i = \bar{X}_i(\epsilon) \nabla \min(\sigma_i)$.

The technical state of the damper is $\epsilon = \bar{X}(\epsilon) \mp 2\sigma$ with 95.45% of confidence factor. For the given case study, the value of the technical state is $\epsilon = 0.71\epsilon_{10} \pm 0.1$ in the four (4) secondary stage vertical dampers (hypothesis ζ_1) with a confidence of 95.45%. This means that the dampers are degraded 29% relative its nominal characteristic.

{Table 4}

9. Conclusions

The OMA-LSCE technique is a suitable technique to evaluate and identify the technical state of the dampers ϵ_i and the operating characteristics of the components of passengers railway vehicles.

The vertical dampers of the secondary suspension stage present a direct influence on the dynamic behavior of the modal shapes, ϕ_2 and ϕ_4 , therefore the different technical states of the damper ϵ_i can be tested and estimated through the dynamic recording in the carbody. This means that from the sensors installed in the carbody that register appropriately the natural frequency Ω it is possible to determine the variation of the damping function of these elements and to infer their degradation or failure.

The dynamic parameters, Ω and ξ , have a high dependence degree over the secondary suspension dampers δ_j .

An experimental model of three (3) measurement points, $\bar{z}_{ql}^*$, $\bar{z}_{ql}^+$, y $\bar{z}_{ql}^o$ obtained from a set of sensors can be used to identify the dynamic parameters, Ω and ξ , in a vehicle with load condition AW0 with the OMA-LSCE method.

A methodology has been proposed and applied for the evaluation of the technical state of the dampers ϵ_i and the identification of hypothesis of suspension elements deterioration ζ_i through measurements of variables under operating conditions of the vehicle.

International standards for railway vehicles define the range for deficient frequency $\omega = [8, 10]\text{Hz}$. The human body is sensible to vertical accelerations [27]; frequencies $\omega \approx 10\text{Hz}$ cause excessive oscillations on ϕ_2 , generating significant deficiency of comfort. Comparing with the values obtained for the analyzed vibration modes ϕ_r and under the different technical states of the damper ϵ_i , the natural frequency is $\Omega < 2\text{Hz}$. Therefore, the degradation of the damping function of the suspension elements does not incur *per se* in violation to the railway standard.

Table 3. Modal parameters identified by EMA and OMA techniques, condition ϵ_0 .

Modal analysis type	Modal shape Ω [Hz]	
	ϕ_2	ϕ_4
EMA	1.47	2.10
OMA	1.46	2.09
Error, ϵ [%]	0.91	0.04

Table 4. Evaluation of technical state ϵ in order to ζ_i .

Modal shape, ϕ_r	Modal parameter		technical state of damper ϵ [--]		
	Description	Value	ζ_1	ζ_2	ζ_3
ϕ_2	Ω [Hz]	1.53	0.70	0.57	0.48
	ξ [%]	2.90	0.70	0.58	0.42
ϕ_4	Ω [Hz]	2.18	0.77	0.61	0.61
	ξ [%]	2.20	0.67	0.75	0.72
Mean value, $\bar{x}_i$			0.71	0.63	0.56
Standard deviation, σ_i			0.04	0.08	0.14

Table 5. Vehicle parameters.

Element	Quantity	Value	Unit
Mass			
Carbody	1	24486.36	kg
Bogie frame	2	6102.44	kg
Motor	4	5551	kg
Electromag. brake	4	704	kg
Traction link	2	--	kg
Axle-wheel set	4	7083.52	kg
Stiffness			
Lineal	1	$k_A = 1.00$	kN/mm
Non-lineal	20	--	kN/mm
Shear	8	$k_x = 2.16$	kN/mm
		$k_y = 2.16$	kN/mm
		$k_z = 12.16$	kN/mm
Axi-directional	2	0.08	kNmm/s
Air stiffness	4	$k_z = 4.52$	kN/mm
		$k_y = 1.04$	kN/mm
Non-lineal damper	13	--	kNmm/s
Busing	36	$k_x = 67.32$	kN/mm
		$k_y = 36E-5$	kN/mm

Element	Quantity	Value	Unit
		$k_z = 72\text{E-}6$	kN/mm
		$k_\theta = 36\text{E-}5$	MNm/rad
		$k_\phi = 2\text{E-}6$	MNm/rad
		$k_\psi = 1\text{E-}5$	MNm/rad
