33

34 **HIGHLIGHTS:**

35 Calls of male rock ptarmigans show individual vocal signatures.

36 These signatures allow acoustic censusing of the number of males present in an area.

37 Acoustic sampling is more accurate than point-count protocol.

38

39 **ABSTRACT:**

40 The cost-effectiveness and reduced human effort employed in setting up acoustic monitoring
41 in the field makes bioacoustics an appealing option for wildlife monitoring. This is especially
42 true for secretive vocal species living in remote places. However, acoustic monitoring still
43 raises questions regarding its reliability when compared to other, human-driven methods. In
44 this study we compare different approaches to count rock ptarmigan males, an alpine bird
45 species which lives at high altitudes. The monitoring of rock ptarmigan populations is
46 traditionally conducted using a point-count protocol, with human observers counting singing
47 males from a set of different points. We assessed the (1) feasibility and (2) reliability of an
48 alternative counting method based on acoustic recordings followed by signal analysis and a
49 dedicated statistical approach to estimate the abundance of males. We then (3) compared
50 the results obtained with this bioacoustics monitoring method with those obtained through the
51 point-count protocol approach over three consecutive years. Acoustic analysis demonstrated
52 that rock ptarmigan vocalizations exhibit an individual stereotypy that can be used to
53 estimate the abundance of males. Simulations, using subsets of our recording dataset,
54 demonstrated that the clustering methods used to discriminate between males based on their
55 vocalizations are sensitive to both the number of recorded signals, as well as the number of
56 individuals to be discriminated. Despite these limitations, we highlight the reliability of the
57 bioacoustics approach, showing that it avoids both observer bias and double counting,
58 contrary to the point-count protocol where this may occur and impair the data reliability.
59 Overall, our study suggests that bioacoustics monitoring should be used in addition to
60 traditional counting methods to obtain a more accurate estimate of rock ptarmigan
61 abundance within Alpine environments.

67

68 1. Introduction

69 Acoustic monitoring is becoming an effective means to assess wildlife diversity, resulting in
70 minimal impact to the environment (Towsey et al., 2014; Sueur and Farina, 2015).
71 Importantly, it enables to focus on species used as bioindicators as well as of patrimonial or
72 economic concern. The use of acoustic monitoring is usually motivated by the difficulty in
73 observing the species because of its secretive behavior or the difficulty in accessing its
74 habitat (Hoodless et al., 2008; Vögeli et al., 2008; Marques et al., 2009; Buxton and Jones,
75 2012; Dugan et al., 2013; Marques et al., 2013; Andreassen et al., 2014; Ulloa, 2016). Levels
76 of investigation range from the simple assessment of species' presence/absence to more
77 complex studies that aim at determining the number of individuals present on an area.
78 Depending on the species, these approaches may require the discrimination of individuals
79 (Terry et al., 2005; Pollard et al., 2010), which is only possible when vocalizations contain
80 individual vocal signatures based on morpho-physical, genetics and/or learning abilities
81 (Kroodsma, 1982; Tibbetts et Dale, 2007; Catchpole et al., 2008; Taylor and Reby, 2010;
82 Nowicki and Searcy, 2014; Tamura et al., 2018).

83 Although acoustic monitoring is promising, it still raises several potential issues: high cost of
84 monitoring material, design of monitoring protocols, analysis of long-duration recorded
85 signals, weather conditions impacting the quality of the data, needs of bioacoustics experts
86 for data analysis, and sensitivity to the density of the species (Budka et al., 2015; Linhart and
87 Šálek, 2017). To the best of our knowledge, acoustic monitoring has not yet replaced other
88 protocols. Point-counts protocols (Lancia et al., 2005) are still largely used to provide
89 estimates of the number of individuals. However, these conventional, human-operated
90 methods are exposed to biases due to inter-individual differences between observers,
91 unpredictability of field conditions, and biological parameters such as species abundance
92 (Tyre et al., 2003; Bart et al., 2004; Lotz and Allen, 2007; Elphick, 2008; Fitzpatrick, 2009).
93 Moreover, individuals of species emitting long-range signals can be counted by several
94 observers simultaneously, leading to double counting and abundance overestimation.
95 Besides, human presence can disturb birds' behavior making them stop singing and leading
96 to population underestimation.

97 While previous works have explored the technical feasibility of acoustic monitoring based on
98 vocal individual signature (Terry and McGregor, 2002; Hartwig, 2005; Grava et al., 2008;
99 Policht et al., 2009; Adi et al., 2010; Feng et al., 2014; Budka et al., 2015, 2018; Peri, 2018a)
100 most field applications were based on sounds recorded from already known individuals
101 (O'Farrell and Gannon, 1999; Peake and McGregor, 2001; Vögeli et al., 2008; Digby et al.,
102 2013; Peri, 2018b). To the best of our knowledge, there is no published study investigating

the generalization and reliability of an acoustic monitoring approach based on individual vocal signatures aimed at estimating the number of individuals in real field conditions. Focusing on the rock ptarmigan *Lagopus muta* in France, the present paper reports a multi-year study aimed at assessing the potential interests, as well as the caveats, of acoustic monitoring by comparing performances of this approach with a traditional point-count methodology.

The rock ptarmigan is a bird species that inhabits the northern parts of Eurasia and North America. In France, its range is restricted to sub-alpine and alpine habitats (altitude > 1800 m) of the Pyrenees and the Alps Mountain ranges (Sale and Potapov, 2013). This species is secretive and difficult to access. It is highly adapted to its environment, has mimetic plumage and vocalizes at dawn and dusk (MacDonald, 1970). Population abundances are decreasing in both the Alps (Imperio et al., 2013; Furrer et al., 2016; Martinoli et al., 2017) and the Pyrenees, where they are threatened by both climate change and habitat transformation (Revermann et al., 2012; Bech et al., 2013). Due to these extreme environmental and selective pressures, rock ptarmigan is often considered as a bioindicator of the ecosystem health, a sentinel and umbrella species for biodiversity conservation of the alpine environments (Sandercock et al., 2005; Hanser and Knick, 2011; Henden et al., 2017).

During the mating season (May-June), males display courtship rituals, which often includes simple, pulsatile vocalizations as well as a peculiar “singing in flight” behavior before dawn (MacDonald, 1970). The flight is hyperbolic, and vocalization starts when the bird reaches the point of highest altitude. Point-count protocols rely on this acoustic behavior to evaluate the number of males after they have established their breeding territories (Bossert, 1977). Although vocalizations are loud and easily heard by an observer, low visibility, birds’ mobility, frequent harsh weather conditions and other constraints associated with the alpine environment are likely to increase the possibility of double counting and overestimation of the monitored population. Conversely, this may also impair song perception by observers (Andreev, 1971). The use of an acoustic monitoring technique could provide a feasible alternative as a response to these difficulties and potential biases. Despite these constraints, rock ptarmigan presents several advantages in terms of monitoring. Vocalizations are easily recognizable, population densities are generally low (around 5 males/km²), and males are mostly located in stable territories which facilitates their localization and recording.

The present study proposes (1) to assess the individual vocal signature embedded in rock ptarmigan males’ calls, (2) to test the feasibility and reliability of a bioacoustic monitoring approach over several years, and (3) to compare the results obtained using this approach to those obtained with a traditional point-count protocol and long-term field observations.

138

139 **2. Material and Methods**

140 We performed this study in 2015, 2016 and 2017, at the ski resort of Flaine (French Alps,
141 Haute-Savoie, 45°59'32.8"N 6°43'44.2"E; altitude: 1600-2500 m).

142

143 *2.1 Counting of singing males*

144 We used three different methods to evaluate males' abundance: a point-count protocol, long-
145 term observations and acoustic monitoring. The latter was followed by signal processing and
146 statistical analysis.

147

148 *Point-count protocol*

149 The counting area was delimited empirically to cover roughly 100 hectares (Fig.1). Previous
150 field observations and literature reviews had suggested that male ptarmigans could be heard
151 at distances of 500-1000 m (Watson, 1965; Bossert, 1977; Marty and Mossoll-Torres, 2012).
152 We selected three counting points, approximately 500 m apart from one another to maximize
153 the listening area (Fig.1). These counting points were located at precisely the same positions
154 over the three-year period of study. The counting procedure followed that proposed by
155 Léonard (1995), which was based on the work of Bossert (1977). Three experienced
156 observers, with previous knowledge of the field (TMC, FS, BMJ; 1 per counting point),
157 accompanied by volunteers, were placed at each point. As ptarmigan males mainly display
158 their acoustic signal early in the morning, the observation periods started at 4.30 a.m. and
159 ended at 5.30 a.m. The observers were positioned 15 min before the beginning of the
160 observation period. Throughout the observation period, each observer noted on an
161 observation form (with a drawn map of the area) the timing, the number and the approximate
162 estimated locations of the vocalizing ptarmigans. At the end of the observation period, BMJ
163 collected all observers' forms.

164 To estimate the total number of males in the area, we counted 1 male for each group of
165 neighboring vocalizations indicated on the maps (each group had to be clearly separated
166 from the others; see Fig. 1). Each male was confirmed by cross-checking the observers'
167 data. To avoid double-counting by two different observers, vocalizations localized nearby and
168 heard at approximately the same time (interval < 20 sec.), were considered identical. We
169 considered the total number of males unambiguously localized as the minimum total number
170 of males. To take into account ambiguous localizations (e.g. when one observer noted two
171 birds on the same location while another observer noted a single one) we defined a

maximum total number of birds by adding these ambiguous males to the minimum total number. We thus defined an estimated interval (min-max) of the total number of males. This procedure was repeated on several consecutive days namely: June 3rd and 4th in 2015 and 2016; June 6th, 7th, 9th in 2017.

Long-term observations and acoustic recordings

After the point-counting days, two bioacousticians (TMC and FS) remained in the field for a period of one month to observe and record all the birds present in the area (recording material: Sennheiser MKH70 shotgun microphones connected to Marantz PMD 660 recorders; sampling rate: 48000 Hz). This was an important long-term observation effort aimed at ensuring a thorough knowledge and identification of each bird present within the area, which may have been acoustically recorded during the point-count protocol. The resulting number of males spotted by this technique therefore represented the expected maximum value that could be deduced using the other methods.

Despite this effort however, we were only able to record birds during 7, 9, and 15 days in 2015, 2016 and 2017 respectively, primarily due to the harsh weather conditions. We used two different strategies in order to build up our bank of recordings:

1) Recording of non-identified birds before sunrise (4.30 a.m. - 6 a.m.), i.e. during the time slot corresponding to the spontaneous singing activity peak. Due to the low ambient luminosity, the recorded males could not be visually observed and identified. The recording data sets were thus named: “unknown datasets”. Each day, both bioacousticians recorded from different locations within the study area to sample a maximum number of males.

2) Recording of identified birds (6 a.m. – around 10 a.m.). In 2017, we equipped 5 males present on the area with GPS solar tags (e-obs GmbH, Grünwald, Germany), and used these tags to pinpoint the males with their individual UHF (Ultra High Frequency) radiofrequencies. One male had already been equipped with a VHF (Very High Frequency) radio-emitter collar since 2015. Two additional males were identified using visual cues only. Both had mated with females and remained within stable and well-defined territories. The combination of direct observations and GPS localizations greatly minimized the risk of mis-identifying or confounding males during recordings. A ninth male had its territory on a neighboring summit (3 km away). As this male was alone on this site and easy to identify, it was thus added to the recording database (total = 9 birds in 2017).

The recording strategy was as follows: after sunrise, when the peak of males’ vocal activity ended, we played back calls from an individual recorded in another area to elicit the focus

male's territorial response. This allowed us to record each focus male while double-checking for its individual identity.

In the preceding years (2015 and 2016), we used the same approach although the results of the field effort were weaker:

- June 2016: 5 males recorded. Two of the males were equipped with GPS tags and 3 other males were identified using visual observations only.

- June 2015: 7 males recorded. One male was equipped with a VHF radiotransmitter necklace; 6 males were identified using visual observations only.

The 2015, 2016 and 2017 recording data sets obtained with this method were named "known datasets".

2.2 Acoustic analysis of recorded signals

Data bank of calls

Rock ptarmigan vocalizations are sequences of pulse trains, with energy spread over a frequency spectrum ranging from 900 to 3700 Hz. There are two major types of calls, namely short and long calls. These differ by the number of successive pulse trains, namely 3 and 4 respectively (MacDonald, 1970; Watson, 1965). For the present study, we focused on the short calls, which are the most frequently recorded (Fig. 2). Our annual data bank of calls consisted of the following:

- 2015: 183 short calls, of which 100 were of sufficient quality (in terms of signal-to-noise ratio) to be analyzed ("unknown" dataset: 75 calls; "known" dataset: 25 calls, 3.6 ± 2.4 calls/male, min = 1 call, max = 8 calls).
- 2016: 249 short calls, with 98 of sufficient quality ("unknown" dataset: 66; "known" dataset: 32 calls, 6.4 ± 2.3 calls/male, min = 4 calls, max = 10 calls).
- 2017: 180 short calls, with 133 of sufficient quality ("unknown" dataset: 52 calls; "known" dataset: 81 calls, 7.1 ± 3.9 calls/male, min = 3 calls, max = 24 calls).

Automatic detection of group of pulses

Due to harsh weather conditions (wind and rain), recorded signals were frequently corrupted by noise. Before performing the automatic detection of pulses, we first filtered the signals with a 950-2700 Hz bandpass filter, and then processed a *wavelet continuous transform*

(WaveleComp R package, Roesch and Schmidbauer, 2018) to optimize the signal-to-noise ratio (see Supplementary Material for details).

After denoising, amplitude pulses were detected using a customized script (Seewave R package, Sueur et al., 2008). The absolute amplitude of the signal was first smoothed using a Daniell kernel (length = 100). The time position of the pulses was then identified using an amplitude threshold fixed at 3 % of the maximum amplitude of the considered signal.

Pulses were gathered in “groups” (G1, G2, G3, see Fig. 2) by automatically measuring intervals between pulses (Fig. 2c) and computing the ratios between two successive intervals (Fig. 2d). Ratios superior to 1.7 characterized boundaries between groups of pulses (Sil1 and Sil2; see Fig. 2b).

Measurement of acoustic parameters

We measured 12 acoustic parameters from groups of pulses G1 and G2 (see list in Table 1). We chose to ignore the G3 group, as the signal-to-noise ratio of this part of the call was usually very weak (this was mostly due to males flying away from the recorder while singing).

The mean acceleration (Acc.G1) was calculated as follows:

$$Acc = \frac{1}{n-2} \sum_{k=1}^{n-2} \frac{1}{Pr_{k+1} - Pr_k} - \frac{1}{Pr_k - Pr_{k-1}}$$

Where n is number of pulses in G1; Pr is the pulse rate and t is the time of occurrence of the pulse's maximum amplitude.

The normalized Pairwise Variability Index ($nPVI$) is an index commonly used in phonetic studies (Grabe and Low 2002) to illustrate the variability between consecutive pairs of intervals:

$$nPVI = 100 \times \sum_{k=1}^{n-1} \left| \frac{Pr_k - Pr_{k+1}}{\frac{(Pr_k + Pr_{k+1})}{2}} \right|.$$

We used continuous wavelet transformation to calculate the peak frequency parameters (Fq1.G1 and Fq2.G1). Since pulse locations in the signal had already been calculated, each pulse was isolated from the original sound, filtered with an 800 Hz -3000 Hz passband filter. For each pulse, wavelet power spectrum was then calculated. The two scales with the maximum power were then selected. The scales were further multiplied by the Fourier factor

6 / (2π) to obtain the classical Fourier periods (Aguilar-Conraria and Soares, 2011) with the corresponding frequencies. The median of each peak frequency was then calculated across the entire pulse train. Overall, medians were preferred to means since they are more conservative and less influenced by possible outliers resulting from analytical errors (e.g. due to rain drops occurring within a pulse group).

2.3. Acoustic space and individual vocal signatures

In order to build a functional tool allowing the acoustic discrimination between rock ptarmigan males, we proceeded as follows: 1) we built a 4-D acoustic space with a dedicated discriminant analysis which optimized separation between males using the 2017 “known” dataset (reference dataset); 2) we used this acoustic space to perform an unsupervised clustering analysis using the reference dataset for tuning the clustering hyperparameters; 3) we applied the workflow (centering, projection in the acoustic space and then tuned clustering) on the 2015, 2016 and 2017 complete data sets to further estimate the number of males present each year.

Acoustic space definition

We analyzed the differences between calls from the individuals of the 2017 “known” dataset (9 identified males) using powered partial least squares discriminant analysis (PPLS-DA, Liland and Indahl, 2009; “pls” R package, Mevik et al., 2016). PPLS-DA enables more accurate analysis of a small sample size with a high number of acoustic parameters, better than the linear discriminant analysis signatures (Hervé et al., 2018), commonly used in studies on animal vocalizations. PPLS-DA calculates new variables as combinations of all centered acoustic variables, leading to a new acoustic space optimizing the discrimination between individuals. The number of dimensions was chosen by model cross validation (Szymańska et al., 2012). The mean classification error rate was established after 100 model cross validations for each number of dimensions (varying between 2 to 11, Fig. 3). We followed an analog method of the elbow method (Cattell, 1966) to assess the optimal number of dimensions and we considered the first four PPLS-DA variables, which define a 4-D acoustic space and explained 36.52 % of the variability (see Results and Fig. 4).

We tested the statistical significance of our PPLS-DA model with a procedure implemented in the RVAideMemoire package (Westerhuis et al. 2008; Hervé, 2018). The PPLS-DA

significance validation is composed of two steps. Firstly, a set of discriminant functions is obtained from a training data set and secondly, these functions are used to test the classification on a validation set. The measure of standard error is obtained by analyzing the correct assignment percentage of 999 random selections of the original data set, which have been divided into a fitting and testing set.

Clustering analysis and bootstrap reliability testing

We used an unsupervised classification method (high dimensional data clustering, HDDC, Bouveyron et al., 2007) to estimate the number of individual males present within the datasets. HDDC has already been applied on acoustic data with some success (Ulloa, 2018). HDDC is known to be consistent and reliable with unbalanced datasets because it is based on gaussian mixture models (Fraley and Raftery, 2002). It is more parsimonious and flexible than gaussian mixture modelling by adding a noise term within the model covariance parametrization. The mixture model aims at identifying the meaningful variables for each cluster and is fitted with the E-M algorithm. The number of mixture components of the model maximizing the Bayesian information Criterion (BIC, Schwarz, 1978) is set as the number of clusters. The E-M algorithm is sensible to the selected random points during its initialization. Thus, we ran the clustering algorithm several times in order to obtain a reliable value for the number of clusters.

The 2017 'known' reference dataset was used for tuning the HDDC hyperparameters ($K = 9$ clusters in 2017; the covariance model M ; the threshold t used to parametrize the dimension of each cluster; see R package HDclassif, Bergé et al., 2012 for details). Each call was represented by its 4 acoustic dimensions previously calculated through PPLS-DA. We tested 10 values of t namely: 0.000001, 0.00001, 0.0001, 0.01, 0.03, 0.05, 0.07, 0.1, 0.15, 0.2 (adapted from Ulloa, 2018) and the 14 possible models of covariance parametrization. Each association of t and M value were tested.

The clustering algorithm was run 100 times for each association. For each run, we measured the similarity between the clustering output and the clustering membership with the adjusted Rand Index (ARI, Hubert and Arabie, 1985; package mclust, Scrucca et al., 2016). The ARI ranges from -1 to 1 and is an indicator of the concordance of two classifications for the same dataset: when $ARI = -1$, the classifications are totally opposed, or different. When $ARI = 0$, the classifications are considered random; when $ARI = 1$, they are identical. The mean ARI was then calculated for the 100 values and the tuning parameters associated with the highest mean were selected. The maximum mean adjusted Rand Index ($ARI = 0.91$) was

found for the simplest covariance model (“abqd”) and a threshold value of 0.1 was assigned. We thus used these tuning parameters.

Once M and t fitted with our data, the reliability of the clustering process was further tested using sub-sets of the 2017 reference ‘known’ dataset. Subsets were built by randomly sampling several various males (random sampling of 1 to 9 males; 900 subsets; 100 trials/subset) or a various total number of calls (random sampling of 20 to 81 calls; 6200 subsets; 100 trials/subset). We tested models with K values ranging from 1 to 20.

2.4 Comparison between counting methods

To assess the number of males through the acoustic analysis of calls, we performed the clustering analysis on each year separately, using the entire datasets obtained by pooling “known” and “unknown” calls (100 trials/year). The male of 2017 that was geographically isolated was however excluded because it was located outside the point-counting area. We calculated the 4 dimensions of each call using the PPLS-DA functions previously defined with the 2017 “known” dataset for each year separately. Each acoustic dataset was centered before its projection in the 2017 acoustic space by subtracting the means of each acoustic variable calculated on the 2017 “known” dataset.

The number of males (i.e. the number of acoustic clusters) estimated for each year through the clustering analysis was then compared with the number of males estimated through the two other counting methods, i.e. 1) the point-count protocol and 2) the long-term observation.

All the acoustic and statistical analysis was performed on R version 3.5.0 (R core team, 2018).

3. Results

3.1 Acoustic discrimination between males and definition of the acoustic space

The PPLS-DA identified significant acoustic differences between ptarmigan males, with 4 significant functions that allowed maximizing individual separation (Fig. 4, mean classification rate = 79 %; min-max classification rate per individual = 0 – 100 %; $p = 0.001$). Table 2 shows the correlation between each of the 4 components, the acoustic variables and shows that all parameter types (pulse number, pulse rate, durations, frequency parameters) contribute towards separating the males.

3.2 Reliability of High Dimensional Data Clustering

To test the reliability of HDDC, we compared the median number of males obtained through resampled HDDC with the actual number of males of each sub-data set. As displayed in Fig. 5, HDDC gives a reliable estimate of the number of recorded males if this number does not exceed 5 individuals. HDDC underestimates the number of recorded males when 6 or more individuals were included in the sub-dataset. It also underestimates the number of recorded males, when the number of vocalizations in the sub-datasets are sampled, and consistently predicts 7 clusters (i.e. 7 individuals) for sub-datasets composed of a minimum of 33 vocalizations (i.e. 41 % of the total number of calls) (Fig. 5b).

3.3 Comparison of counting methods' reliability

In 2017 and 2016, the most congruent results were given by the acoustic monitoring and long-term observation. In both years, the point-count protocol resulted in a lower estimation than the two other counting methods. Still, the long-term results were reached by the point-count intervals for at least one day per year. Estimation through the point-count protocol appears to be highly dependent on the day of observation (this is particularly obvious in 2017, with an estimate of 5-8 males on the first day *versus* 4-5 males on the second day).

The 2015 results differed significantly from those of 2016 and 2017, with an apparent underestimation of the number of males through the acoustic monitoring method compared to long-term observations. However, the distribution is widespread and looks bimodal, with the second mode (6 clusters) being close to the actual number of males (7 individuals). This can be clearly seen in Fig. 6 which displays the number of males estimated by each counting method (point-count protocol, long-term observation, acoustic monitoring).

4. Discussion

4.1 Does the acoustic space built from recordings encompass the vocal variability of rock ptarmigan males?

The relative inconsistency of individual males' vocal signature might limit the bioacoustics approach. Although the mean PPLS-DA classification rate of recorded calls was around 80%, individual rates differed greatly among males (from 0% to 100%). Moreover, the discriminant functions used to build the acoustic space explained only 36% of the total

acoustic variability of calls. A significant proportion of the variability remains out of reach, suggesting that individual identity is not the only factor driving the calls' structure. Rock ptarmigan' vocalizations are sequences of stereotyped pulses with few frequency modulations. The acoustic variation between individuals may thus be reduced when compared to other bird species with more complex signals. Ptarmigan are non-oscine birds (Kroodsma et al., 1982; Slater, 1989), and their vocalizations thus lack then the individual variability that could have been induced by song learning. Inter-individual differences in ptarmigan acoustic signals mostly result from differences in their genetic background and their physiological conditions. It is known that ptarmigan males are highly philopatric and closely related genetically in the Alps at large scale (Caizergues et al., 2003). In addition to this, a genetic study of a closely related species, the red grouse (*Lagopus lagopus scoticus*), showed that males were highly related at local scales (Piertney et al., 1998). The genetic variability between rock ptarmigan males is thus rather low. Moreover, the highly variable alpine weather conditions should promote great annual variations in food availability, especially due to snow cover and the timing of snow melt (Körner, 2003; Edwards, 2007; Jonas, 2008). Thus, males' physiological state might be different both between individuals (e.g. depending on the individual food intake in each territory) and from year to year within individuals (depending on the availability of resources). The variability from year to year is of special concern as vocalizations from the same male could be very different each year, thus impairing recapturing males over consecutive years using acoustics only. For this reason, we considered each year independently within the present study.

Our analysis demonstrates that, despite these potential limitations and thanks to their low densities in France (few males present on the same area), it is possible to rely on individual vocal signatures to identify local rock ptarmigan males (Linhart and Šálek, 2017) and, ultimately, to count them. The first requirement is to include only high-quality recordings in the analysis step (recordings are regularly corrupted by background noise, mostly induced by wind). Besides, analysis should be mainly performed on the temporal acoustics parameters, since these are less influenced by noise than the frequency cues. These conservative choices and the fact that, by design, PPLS-DA optimizes the separation between males and not the explained variability, can partly explain the low percentage found. Nevertheless, we were still able to separate the males well enough for our purpose.

4.2 High dimensional data clustering

A second potential limitation of the bioacoustics method may arise in cases where some males are represented by only a few recordings, resulting in unbalanced recording datasets.

HDDC is a model-based clustering, fitted by maximizing log-likelihood estimation (MLE), itself based on the probabilities of clusters membership. The likelihood will tend to favour clusters forming large and homogenous groups of points (Fraley and Raftery, 1998). When the recording dataset is strongly unbalanced between males, individuals with few vocalizations can be confounded (i.e. included in the same cluster) with other males that show close vocalization characteristics. One of the males was overrepresented in the 2017 “known” dataset and its calls formed a cluster that incorporated vocalizations from some other males. This resulted in an underestimated total number of individuals. After removing this male from the dataset (for comparing between methods), the number of estimated clusters was higher and more reliable. Unbalanced situations are more likely to arise when the recording effort is mitigated, as was the case in 2015. This caused HDDC to underperform, resulting in an underestimation of the number of males present in the observation area. Such a difference can be explained when looking at the call’s clusters obtained through the HDDC method for each year, using both ‘known’ and ‘unknown’ data sets (Fig. 7). In 2015, the vocalizations were mostly from unknown emitters. As a result, clusters strongly overlapped each other. Conversely, 2016 and 2017 vocalizations are more clearly separated into homogenous groups. The recording sampling effort must then be homogeneous over the whole study area and cautiously planned to optimize the representativity of recording banks (Heupel et al., 2006).

4.3 Sampling effort and balance

An adequate acoustic dataset needs a major field effort, due to frequent harsh weather conditions and difficulties associated with approaching males’ territories. Despite these constraints, comparable results were found between bioacoustics and long-term methods. Long-term observations seem the most reliable approach, although not feasible on a regular schedule given the required workforce. However, most of the vocalizations were obtained using playbacks and males were recorded directly within their territories (“known” datasets). Marginal males were included (Fig. 1) as we assumed that they could be heard and could fly inside the study area. The area of interest was therefore slightly larger than the area covered by the point-count protocol. This increased the probability of male detection during the acoustic monitoring compared to the point-count protocol. Conversely, point-count monitoring appears to be less accurate, with a greater variability of males’ abundance estimations between counting days.

The reduced reliability of the point-count census is not surprising, given that observers focus generally on only one observation day. We extended the counting period for a few days to show the variability of this method in this study. Weather conditions (e.g. wind speed) and variation in males' motivation to vocalize may impair the detectability of males. Moreover, the number of males present in the area fluctuates through the season and between observation days. In contrary to northern latitudes (Unander and Steen, 1985; Cotter, 1999), ptarmigan males differ in their arrival dates depending on their mating status. Mated males return to their territory in late summer / autumn, while single males arrive only in spring of the subsequent year. Snow cover plays an important role in the availability of territories and reproductive success of the species (Novoa et al., 2008) by delaying the males' arrival (one of the 2015 males equipped with VHF was not present in 2016 –a year during which snow covered its territory- but arrived in late June in 2017, when the snow cover of its territory started to dissipate).

Point-count census is a “one-shot” process: it estimates the number of males at a given day whereas bioacoustics and long-term observation estimations are obtained over larger time periods. The point-count protocol is therefore not able to capture changes throughout the mating season. In practice, only long-term monitoring using direct observations or acoustic recordings could overcome this variability.

In addition, our study was able to test the reliability of the census method based on the number of individuals and the number of signals taken into consideration. We showed that a minimum number of sampled vocalizations were necessary (approximately 33 vocalizations for 9 individuals, Fig. 5B) to ensure a consistent assessment of males' number. Although the efficiency of the clustering method is density dependent, this is on a smaller scale than those of classical counting methods (Budka et al., 2015; Linhart and Šálek, 2017). To apply our analysis methodology across populations in different locations, we would probably need to consider a range of higher signal diversities. The generalization of our study would thus need to train our statistical model (PPLS-DA) with recordings from identified males, from other rock ptarmigan populations, to encompass greater signal variability and to avoid staying at local scale variability.

4.4 Is bioacoustics monitoring a good solution for rock ptarmigan population monitoring?

The choice of a monitoring method is the result of a balance between the scale of the study and the expected results. At a fixed cost, the same number of automatic recorders allow to gather precise information regarding males' abundance and locations within a restricted area or could provide simple presence/absence survey of a wider region. Besides, the

bioacoustics approach could enable the censusing of more areas without requiring an increase of the number of observers and/or days of observation. This may be particularly advantageous in large and remote mountain massifs where rock ptarmigan habitats can be situated in remote areas.

Acknowledgements

This research was supported by the University of Lyon / Saint-Etienne (PhD stipend to TMC, research support), the ONCFS (Office National de la Chasse et de la Faune Sauvage), CeLyA (Centre Lyonnais d'Acoustique) and the Institut universitaire de France (NM). The Domaine Skiable de Flaine logistically supported the study. We would like to warmly thank

Fabrice Antoine, Marc Arvin-Berod, Thomas Betton, Loïc Berger, Sébastien Bernard, Michel Bouchard, Félicien Bros, Léna De Framond Benard, Etienne Marlé, Joël Prince, Aymeric Richard, Fanny Ryback, and Théophile Yeme who willingly volunteered to participate into the point-counts. We thank two anonymous reviewers for their helpful comments. The authors declare no conflict of interest.

Author contribution statement

TMC, FS, BMJ, JFD, MMI, FN, PA, CN and NM conceived the ideas and designed the methodology; BMJ captured the males, equipped the GPS collar and organized the point-count protocols. TMC and FS collected the acoustic data; TMC, MMI, FN analyzed the data; TMC, FS and NM wrote the manuscript. All authors contributed critically to the drafts and gave final approval for publication.
