Abstract

Transport equations for (i) the rate W of product creation and (ii) its Favre-averaged value $\tilde{W}$ are derived from the first principles by assuming that W depends solely on the temperature and mass fraction of a deficient reactant in a premixed turbulent flame characterized by the Lewis number Le different from unity. The right hand side of the transport equation for $\tilde{W}$ involves seven unclosed terms, with some of them having opposite signs and approximately equal large magnitudes when compared to the left-hand-side terms. Accordingly, separately closing each term does not seem to be a promising approach, but a joint closure relation for the sum $\overline{T_\Sigma}$ of the seven terms is sought. For this purpose, theoretical and numerical investigations of variously stretched laminar premixed flames characterized by $Le < 1$ are performed and the linear relation between T_Σ integrated along the normal to a laminar flame and a product of (i) the consumption velocity u_c and (ii) the stretch rate $\dot{s}_w$ evaluated in the flame reaction zone is obtained. Based on this finding and simple physical reasoning, a joint closure relation of $\overline{T_\Sigma} \propto \overline{\rho W \dot{s}}$ is hypothesized, where ρ is the density and $\dot{s}$ is the stretch rate. The joint closure relation is tested against 3D DNS data obtained from three statistically 1D, planar, adiabatic, premixed turbulent flames in the case of a single-step chemistry and $Le = 0.34, 0.6$, or 0.8 . In all three cases, agreement between $\overline{T_\Sigma}$ and $\overline{\rho W \dot{s}}$ extracted from the DNS is good with exception of large ($\bar{c} > 0.4$) values of the mean combustion progress variable $\bar{c}$ in the case of $Le = 0.34$. The developed linear relation between $\overline{T_\Sigma}$ and $\overline{\rho W \dot{s}}$ helps to understand why the leading edge of a premixed turbulent flame brush can control its speed.

Keywords: premixed turbulent combustion, mean reaction rate, Lewis number, turbulent flame speed, modeling, DNS

Declarations of interest: none

1. Introduction

The most important peculiarity of turbulent combustion of lean hydrogen-air mixtures consists of an abnormally large (when compared to hydrocarbon-air mixtures burned under similar conditions) ratio of turbulent, S_t , and laminar, S_L , flame speeds. This phenomenon is well documented in numerous experiments reviewed elsewhere [1-3], see also Refs. [4,5] as recent examples. The same phenomenon is also documented for lean turbulent flames of various $H_2/CO/CH_4/O_2/N_2$ mixtures [6-11], but the magnitude of the effect is decreased when the mole fraction of hydrogen in the fuel blend is decreased by retaining the same equivalence ratio.

In qualitative discussions, the considered phenomenon is commonly attributed to diffusive-thermal and preferential diffusion effects, which can strongly increase the local burning rate by significantly increasing the local temperature and equivalence ratio in highly curved and strained reaction zones, as discussed in details elsewhere [1-3]. The theory of such effects has yet been developed solely for the laminar premixed flames [12-14], with the focus of the theory being placed on the difference in the molecular diffusivity D of the deficient reactant (e.g., hydrogen in a lean hydrogen-air mixture) and the heat diffusivity κ of the mixture. This difference is commonly characterized with the Lewis number $Le = \kappa/D$, which is about 0.3-0.4 for very lean hydrogen-air mixtures and is larger, but is less than unity for lean $H_2/CO/CH_4/O_2/N_2$ mixtures. Accordingly, the aforementioned abnormally large ratio of S_t/S_L in lean hydrogen-air or $H_2/CO/CH_4/O_2/N_2$ flames is typically discussed in terms of a strong increase in S_t with decreasing Le [1-3].

Although the aforementioned diffusive-thermal and preferential diffusion effects are widely recognized to be the governing physical mechanisms of the well-documented increase in S_t with decreasing Le , the phenomenon remains to be one of the major poorly resolved fundamental issues in the combustion science. Indeed, quantitative prediction of a large ratio of S_t/S_L at a low Le still challenges the combustion community and the vast majority of numerical models of premixed turbulent flames, reviewed elsewhere [15-19], either disregard the influence of Lewis number on turbulent burning rate or invoke highly empirical fits.

The present work aims at filling this gap by (i) extending a recently introduced approach [20-22] to numerical modeling of premixed turbulent combustion to the case of $Le \neq 1$ and (ii) validating the extended approach against Direct Numerical Simulation (DNS) data obtained from premixed turbulent flames characterized by $Le < 1$. The approach directly addresses transport equations for reaction rate W and its Favre-averaged value $\tilde{W}$, but has yet been restricted to the case of $Le = 1$ [20-22]. It is worth remembering that averaging reaction rates subject to fluctuations in the local temperature and concentrations is on the most critical issue of the turbulent combustion theory even in the case of $Le \neq 1$ and the recently introduced transport equations for W and $\tilde{W}$ offer new opportunities to make a progress in this area.

The structure of the paper is as follows. In the next section, transport equations for W and $\tilde{W}$ are derived in the case of $Le \neq 1$. In the third section, the former equation is applied to various stretched laminar premixed flames. In the fourth section, based on analytical and numerical results obtained for the laminar flames, a joint closure relation for all terms on the Right Hand Side (RHS) of the transport equation for $\tilde{W}$ is proposed to be used. The joint closure relation is validated by analyzing DNS data in the fifth section, followed by conclusions.

2. Derivation

Let us assume that the state of the mixture is characterized with (i) the combustion progress variable $c = 1 - Y/Y_u$ and (ii) the normalized temperature $\theta = (T - T_u)/(T_a - T_u)$, i.e., $\rho = \rho(c, \theta)$, $W = W(c, \theta)$, etc. Here, Y is the mass fraction of the deficient reactant, T is the temperature, T_a is the adiabatic combustion temperature (note that θ may be greater than unity if $Le < 1$), ρ is the mixture density, subscripts u and b designate unburned and burned mixture, respectively. The invoked

assumptions are typical, e.g., in theoretical studies of stretched laminar flames [12-14]. The assumptions hold, e.g., in the adiabatic, low-Mach-number, single-step-chemistry¹ case.

Applying a chain rule to express temporal and spatial derivatives of $W = W(c, \theta)$ as functions of temporal and spatial derivatives of c and θ

$$\rho \partial_t W + \rho \mathbf{u} \cdot \nabla W = W_c(\rho \partial_t c + \rho \mathbf{u} \cdot \nabla c) + W_\theta(\rho \partial_t \theta + \rho \mathbf{u} \cdot \nabla \theta) \quad (1)$$

and using the following transport equations

$$\rho \partial_t c + \rho \mathbf{u} \cdot \nabla c = \nabla \cdot (\rho D \nabla c) + \rho W, \quad (2)$$

$$\rho \partial_t \theta + \rho \mathbf{u} \cdot \nabla \theta = Le \nabla \cdot (\rho D \nabla \theta) + \rho W \quad (3)$$

to transform the terms in parentheses on the RHS of Eq. (1), we arrive at

$$\begin{aligned} \rho \partial_t W + \rho \mathbf{u} \cdot \nabla W &= W_c[\nabla \cdot (\rho D \nabla c) + \rho W] + W_\theta[Le \nabla \cdot (\rho D \nabla \theta) + \rho W] \\ &= \nabla \cdot (\rho D W_c \nabla c) - \rho D \nabla c \cdot \nabla W_c + \rho W W_c + Le \nabla \cdot (\rho D W_\theta \nabla \theta) - Le \rho D \nabla \theta \cdot \nabla W_\theta + \rho W W_\theta. \end{aligned} \quad (4)$$

Here, ∂_t designates partial derivative with respect to time, $\mathbf{u}$ is the flow velocity vector, W_c and W_θ are the first-order partial derivatives of the rate W with respect to c and θ , respectively. Subsequently, application of a chain rule $\nabla \Omega = \Omega_c \nabla c + \Omega_\theta \nabla \theta$ to $\Omega = W$, $\Omega = W_c$, and $\Omega = W_\theta$ yields

$$\begin{aligned} \rho \partial_t W + \rho \mathbf{u} \cdot \nabla W &= \nabla \cdot (\rho D \nabla W) + (Le - 1) \nabla \cdot (\rho D W_\theta \nabla \theta) - W_{cc} \rho D \nabla c \cdot \nabla c \\ &\quad - W_{c\theta} \rho D \nabla c \cdot \nabla \theta - Le W_{\theta\theta} \rho D \nabla \theta \cdot \nabla \theta - Le W_{c\theta} \rho D \nabla c \cdot \nabla \theta + \rho W W_c + \rho W W_\theta, \end{aligned} \quad (5)$$

where W_{cc} , $W_{c\theta}$, and $W_{\theta\theta}$ are the second-order derivatives with respect to c and c , c and θ , θ and θ , respectively. Finally, using the continuity equation

$$\partial_t \rho + \nabla \cdot (\rho \mathbf{u}) = 0, \quad (6)$$

we arrive at

$$\begin{aligned} \partial_t (\rho W) + \nabla \cdot (\rho \mathbf{u} W) &= \nabla \cdot (\rho D \nabla W) + (Le - 1) \nabla \cdot (\rho D W_\theta \nabla \theta) - W_{cc} \rho D \nabla c \cdot \nabla c \\ &\quad - (1 + Le) W_{c\theta} \rho D \nabla c \cdot \nabla \theta - Le W_{\theta\theta} \rho D \nabla \theta \cdot \nabla \theta + \rho W W_c + \rho W W_\theta \equiv T_\Sigma. \end{aligned} \quad (7)$$

Ensemble averaging of Eq. (7) yields

$$\begin{aligned} \partial_t (\overline{\rho W}) + \overline{\nabla \cdot (\rho \mathbf{u} W)} &= \overline{\nabla \cdot \rho D \nabla W} + \overline{(Le - 1) \nabla \cdot \rho D W_\theta \nabla \theta} - \overline{W_{cc} \rho D \nabla c \cdot \nabla c} \\ &\quad - \overline{(1 + Le) W_{c\theta} \rho D \nabla c \cdot \nabla \theta} - \overline{Le W_{\theta\theta} \rho D \nabla \theta \cdot \nabla \theta} + \overline{\rho W W_c} + \overline{\rho W W_\theta} \equiv \overline{T_\Sigma}. \end{aligned} \quad (8)$$

If $Le = 1$, then, the rate W depends solely on c . Consequently, $W_\theta = W_{c\theta} = W_{\theta\theta} = T_3 = T_5 = T_6 = T_8 = 0$ and Eqs. (7) and (8) reduce to transport equations derived and studied earlier [20-22]. In this case, terms $\overline{T_4}$ and $\overline{T_7}$ dominate in Eq. (8), i.e., their signs are opposite and their magnitudes are much larger than the magnitudes of other terms or $|\overline{T_4} + \overline{T_7}|$.

¹ A set of transport equations for reaction rates can also be derived in the context of complex chemistry. Such a detailed and complex study will be undertaken after thorough investigation of relatively simple cases.

Accordingly, development of separate closure relations for $\overline{T_4}$ and $\overline{T_7}$ does not seem to be promising, because even small errors in evaluating any of the two terms may be large when compared to $|\overline{T_1}|$ or $|\overline{T_\Sigma}|$. To resolve the problem, a joint closure relation for $\overline{T_2} + \overline{T_4} + \overline{T_7}$ was developed [20,21] based on studies of stretched laminar premixed flames. In the present paper, the same approach is extended to flames characterized by $Le \neq 1$. For this purpose, behavior of T_Σ in stretched laminar premixed flames is analytically and numerically explored in Sect. 3. Then, results obtained from the laminar flames are utilized to develop a joint closure relation for the sum $\overline{T_\Sigma}$ of all terms on the RHS of Eq. (8) in turbulent flames.

3. Stretched laminar premixed flames

3.1. Statement of the problem

Following [20,21], let us consider four simple problems widely used in studies of stretched laminar premixed flames. These are (1) an expanding spherical flame, (2) an expanding cylindrical flame, (3) a steady strained flame with a cylindrical surface, and (4) a steady strained planar flame. If, in cases (3) and (4), all flame and flow characteristics with exception of the transverse (parallel to the flame surface) velocity v are assumed to be constant in the transverse direction in the vicinity of the flow symmetry axis (normal to the flame surface), then, transport equations that model all four flame types can be written in the same form

$$\frac{\partial}{\partial t}(\varrho\Phi) + \rho\varrho\Phi + \frac{1}{r^k}\frac{\partial}{\partial r}(r^k\varrho v\Phi) = \frac{1}{r^k}\frac{\partial}{\partial r}\left(r^k\varrho^{1-m}d_\Phi\frac{\partial\Phi}{\partial r}\right) + \varrho S_\Phi, \quad (9)$$

e.g., see Ref. [23]. Here, $\Phi = \{1, g, c, \theta\}$, $d_\Phi = \{1, D_u, D_u, LeD_u\}$, $S_\Phi = \{0, -g^2 + J/\varrho, \varrho W, \varrho W\}$, $\varrho = \rho/\rho_u$ is the normalized density, g is rate of strain, $k = \{0, 1, 2\}$ for planar, cylindrical, and spherical flames, respectively ($g = 0$ if $k = 2$), and m is a power exponent of the temperature dependence of the diffusivity D .

The boundary conditions read

$$\begin{aligned} v(0, t) = \frac{\partial g}{\partial r}(0, t) = \frac{\partial c}{\partial r}(0, t) = \frac{\partial \theta}{\partial r}(0, t) = 0, \\ \frac{\partial c}{\partial r}(r \rightarrow \infty, t) = \frac{\partial \theta}{\partial r}(r \rightarrow \infty, t) = 0, \quad g(r \rightarrow \infty, t) = J. \end{aligned} \quad (10)$$

3.2. Theoretical study

Application of a method used in Sect. 2 to Eq. (9) written for $\Phi = \{1, c, \theta\}$ yields

$$\frac{\partial}{\partial t}(\rho W) + \rho g W + \frac{1}{r^k}\frac{\partial}{\partial r}(r^k\rho v W) = T_\Sigma, \quad (11)$$

where the term T_Σ is re-written in the spherical or cylindrical coordinate framework in cases (1) or (2) and (3), respectively.

Multiplication of Eq. (11) with r^k , followed by integration from $r=0$ to ∞ and multiplication with R_f^{-k} results in

$$\frac{1}{R_f^k} \frac{d}{dt} (\rho_u R_f^k u_c) + \frac{1}{R_f^k} \int_0^\infty \rho g W r^k dr = \frac{1}{R_f^k} \int_0^\infty r^k T_\Sigma dr, \quad (12)$$

where

$$u_c = \frac{1}{\rho_u R_f^k} \int_0^\infty r^k \rho W dr \quad (13)$$

is the consumption velocity and R_f is a flame coordinate associated, e.g., with the peak reaction rate [24].

Because the reaction zone is thin in a typical laminar flame, variations of the strain rate within the zone may be neglected to the leading order and, consequently, g may be moved outside the integral on the Left Hand Side (LHS) of Eq. (12). Accordingly,

$$\frac{1}{R_f^k} \int_0^\infty r^k T_\Sigma dr = \rho_u \frac{du_c}{dt} + \left(\frac{k}{R_f} \frac{dR_f}{dt} + g_W \right) \rho_u u_c = \rho_u \frac{du_c}{dt} + \rho_u u_c \dot{s}_W \quad (14)$$

where $\dot{s}_W$ is the local stretch rate at the reaction zone. In weakly stretched flames commonly addressed by the theory [12-14], $u_c \approx S_L$ and, therefore, the time derivative on the RHS of Eq. (14) may be skipped. Consequently,

$$\frac{1}{R_f^k} \int_0^\infty r^k T_\Sigma dr \approx \rho_u u_c \dot{s}_W. \quad (15)$$

Equation (15) was earlier derived and used to close the term $\overline{T_\Sigma}$ on the RHS of Eq. (8) in the case of $Le = 1$ [20]. In Sect. 4, Eq. (15) will be adapted to close the sum $\overline{T_\Sigma}$ of all terms on the RHS of Eq. (8) in a turbulent flow.

3.3. Numerical results

To test the theoretical Eqs. (14) and (15), Eqs. (9) and (10) were numerically solved using an in-house code [23] applied earlier to various problems, e.g., see Refs. [20,21,23]. The initial conditions described a small pocket of adiabatic combustion products. The flame coordinate R_f was obtained from a constraint of $W[r = R_f(t), t] = \max\{W(r, t)\}$ at each instant t [24]. Because the laminar flame thickness was small and almost constant in the studied flames, computed results were weakly sensitive to the choice of R_f .

In the laminar flame simulations, all thermo-chemical characteristics were set equal to values used in the DNS discussed in Sect. 5.1. In particular, the Lewis number was set equal to 0.34, 0.6, or 0.8, a ratio of $\rho_u S_L \delta_{th} / (Le \rho D)$ was set equal to 1.75, and

$$W = B(1 - c) \exp \left[-\frac{6\sigma(1 - \theta)}{\sigma - (\sigma - 1)(1 - \theta)} \right]. \quad (16)$$

Here, $\sigma = \rho_u / \rho_b = 5.5$ is the density ratio, and the rate constant B depends on Le in order to obtain desired laminar flame speed and thermal flame thickness $\delta_{th} = 1 / \max\{|\nabla \theta|\}$. The numerical results were normalized using ρ_u , S_L , and δ_{th} , which

were independent of Le , because B was tuned accordingly. The value of $Le = 0.34$ is associated with very lean hydrogen-air flames, whereas the two other values of Le are associated with lean $H_2/CO/CH_4/O_2/N_2$ mixtures.

Fig. 1. The LHS of Eq. (14), see lines, and the term $\rho_u du_c/dt$, open circles and triangles, vs. $\rho_u u_c \dot{s}_W$ in cases of (a) $Le = 0.34$, (b) $Le = 0.6$, and (c) $Le = 0.8$. All quantities are normalized using ρ_u , S_L , and δ_{th} . 1 - expanding spherical flame ($k = 2, J = 0$), 2 - expanding cylindrical flame ($k = 1, J = 0$), 3 - steady strained cylindrical flame ($k = 1$, various J), 4 - steady strained planar flame ($k = 0$, various J).

Computed dependencies of the LHS of Eq. (14), see lines in Fig. 1, and the unsteady term $\rho_u du_c/dt$, see open circles and triangles, on $\rho_u u_c \dot{s}_W$ (i) validate the linear Eq. (15) for variously strained steady flames, see dotted-dashed and dotted lines, and for weakly stretched ($u_c \dot{s}_W < S_L^2/\delta_{th}$) expanding flames, see solid and dashed lines, but (ii) show that the unsteady term $\rho_u du_c/dt$ plays a role in highly stretched expanding flames, with the effect magnitude being increased with decreasing Le . For the goals of the present work, the most important message from Fig. 1 consists of the linear relation between the integrated term T_Σ , i.e., the LHS of Eq. (14), and $\rho_u u_c \dot{s}_W$ in a wide range of stretch rates for different flame configurations. The coefficient of proportionality is very close to unity for the stationary flames, see dotted-dashed and dotted lines, but is slightly less than unity for expanding flames at high stretch rates, see solid and dashed lines, due to the unsteady term, see open circles and triangles, on the RHS of Eq. (14).

4. A joint closure relation

In a recent paper [20], Eq. (15) was theoretically and numerically obtained for stretched laminar premixed flames characterized by $Le = 1$ and a simple joint closure relation

$$\partial_t(\bar{\rho}\tilde{W}) + \nabla \cdot (\bar{\rho}\mathbf{u}\tilde{W}) = \bar{T}_\Sigma \approx \bar{\rho}\tilde{W}\dot{s} = \bar{\rho}\tilde{W}\langle\dot{s}\rangle_W \quad (17)$$

was proposed to be used. Here, $\langle\dot{s}\rangle_W = \langle\nabla \cdot \mathbf{u} - \mathbf{n}\mathbf{n}:\nabla\mathbf{u} + S_d\nabla \cdot \mathbf{n}\rangle_W$ is the stretch rate conditioned to reaction zones, $S_d = [\nabla \cdot (\rho D \nabla c) + \rho W]/(\rho|\nabla c|)$ is the displacement speed, $\mathbf{n} = -\nabla c/|\nabla c|$ is the unit normal vector, and $T_3 = T_5 = T_6 = T_8 = 0$ in $\bar{T}_\Sigma$ in Eq. (8) in the earlier case of $Le = 1$. Subsequently, Eq. (15) was validated [20,21] against three sets of DNS data obtained earlier by two independent research groups under substantially different conditions associated either with the flamelet regime or with the thin reaction zone regime of premixed turbulent combustion [25]. All these data were computed at $Le = 1$.

The physical reasoning for hypothesizing Eq. (15) at $Le = 1$ were as follows [20]. As the analysis of stretched laminar flames shows that T_Σ in Eq. (7) yields $\rho_u u_c \dot{s}_W$ after integration along the normal to a laminar flame, one may assume that $\bar{T}_\Sigma \propto \gamma_r \rho_u u_c \dot{s}_W / \delta_r$, where γ_r is the probability of finding reaction zones and the reaction zone thickness δ_r is obtained from transformation of integration over c using a probability density function $P(c)$ to integration along local normal direction to the reaction zone [20]. Similarly, $\bar{\rho}\tilde{W} \propto \gamma_r \rho_u u_c / \delta_r$, and, consequently, $\bar{T}_\Sigma \propto \bar{\rho}\tilde{W}\dot{s}$.

Equation (15) and almost straight lines shown in Fig. 1 allow us to extend the previous analysis [20,21] invoking basically the same physical reasoning. Accordingly, based on Eq. (15) and Fig. 1, the sum $\bar{T}_\Sigma$ of all terms on the RHS of Eq. (8) is hypothesized to be equal to a product $\bar{\rho}\tilde{W}\langle\dot{s}\rangle_W$ of the mean mass rate $\bar{\rho}\tilde{W}$, whose transport is modeled by Eq. (8), and the stretch rate $\langle\dot{s}\rangle_W$ conditioned to the reaction zone, which characterizes the local flame turbulence-interaction. Consequently, the simple joint closure relation given by Eq. (17) may be applied to flames characterized by $Le < 1$, with S_d and $\mathbf{n}$ being eventually substituted with $S_{d,\theta} = [Le\nabla \cdot (\rho D \nabla \theta) + \rho W]/(\rho|\nabla \theta|)$ and $\mathbf{n}_\theta = -\nabla \theta/|\nabla \theta|$, respectively. It is worth stressing that the developed approach does not involve any tuning coefficient different from unity. Contrary to a usual flamelet approach, which is based on an assumption that the entire flamelets in a turbulent flow retain the structure of (stretched) laminar flames, the present approach invokes a similar hypothesis only for the reaction zone. Accordingly, the domain of validity of the present approach is expected to be wider when compared to a flamelet approach, because the reaction zone is typically thinner and is less perturbed by small-scale turbulent eddies when compared to the flamelet preheat zone. This hypothesis requires further validation in future analyses.

It is also worth noting that Eq. (17) does not solve the problem of closing the RHS of Eq. (8), because the conditioned stretch rate $\langle\dot{s}\rangle_W$ still requires a closure relation. Nevertheless, Eq. (17) appears to be the crucial step to solving the problem, as a sum of seven unclosed terms, which counterbalance one another almost completely, is reduced to a single term. The present approach follows the pioneering ideas by Kolmogorov [26], based on which a widely used closed transport equation for the mean rate $\bar{\epsilon}$ of the dissipation of turbulent kinetic energy $\bar{k}$ was developed [27]. Indeed, the exact transport equation

for $\bar{\epsilon}$ involves two unclosed dominating terms, which have opposite signs and whose magnitude is increased by Re_t and is unbounded at $Re_t \rightarrow \infty$ [28]. However, Kolmogorov [26] proposed to explore the two terms jointly and hypothesized that the sum of them was proportional to $\bar{\epsilon}^2/\bar{k}$ and, therefore, was bounded at $Re_t \rightarrow \infty$. As stressed by Spalding [27], these pioneering ideas laid foundation of a family of two-equation models of turbulence. The joint closure relation given by Eq. (17) follows similar ideas by also utilizing results of laminar flame studies in Sect. 3.

5. Validation

5.1. DNS attributes

Because DNS data analyzed in the following were discussed in details in various papers, e.g., see Refs. [29-33] and references quoted therein, we will restrict ourselves to a brief summary of the simulations.

The cases considered here were simulated using a well-known DNS code SENGa [34], which solved the standard governing equations of mass, momentum, energy, and combustion progress variable written in a non-dimensional form. Combustion chemistry was reduced to a single reaction, with the used thermo-chemical parameters being specified in Sect. 3.3, see Eq. (16). A cubic domain of $24.1\delta_{th} \times 24.1\delta_{th} \times 24.1\delta_{th}$ was discretised by a uniform Cartesian grid of $230 \times 230 \times 230$ points. The spatial discretisation and explicit time advancement were carried out by high-order finite-difference (10^{th} order for internal points, with the order of differentiation gradually reducing to a one-sided 2^{nd} order scheme at the non-periodic boundaries) and Runge-Kutta (3^{rd} order) schemes. The boundaries in the direction of mean flame propagation (here, x -direction) were non-reflecting and were specified according to the Navier-Stokes Characteristic Boundary Condition scheme [35]. The transverse boundaries were periodic. The initial turbulent field was generated using a pseudo-spectral method [36] which yielded a homogeneous isotropic distribution of velocity fluctuations. At $t = 0$, this turbulence field was superimposed on a steady-state unstrained laminar-flame solution. The flame-turbulence interaction evolved under decaying turbulence. Three ($Le = 0.34, 0.6$, and 0.8) flames were studied for the initial $u'/S_L = 7.5$ and normalized longitudinal integral length scale $l/\delta_{th} = 2.5$. The initial Damköhler number $Da = S_L l / (\delta_{th} u') = 0.33$, Karlovitz number $Ka = (u'/S_L)^{1.5} (l/\delta_{th})^{-0.5} = 13$, and turbulent Reynolds number $Re_t = u' l_t / \nu_u = 113$, where $l_t = \bar{k}^{3/2} / \bar{\epsilon}$. The simulations were continued for 3.34 initial eddy turnover times l/u' . At that time, u'/S_L (or l/δ_{th}) decreased (increased) by 50% (70 %) of the initial value.

These simulations yielded a strong increase in S_t/S_L with decreasing the Lewis number ($S_t/S_L = 2.5, 4.6$, and 13.7 at $Le = 0.8, 0.6$, and 0.34 , respectively [29]), in line with various experimental data reviewed elsewhere [1-3]. Accordingly, the DNS data are well appropriate for the major goal of the present study.

5.2. Results and discussion

Figure 2 shows that, as expected, terms $\overline{T_5}$, $\overline{T_6}$, $\overline{T_7}$, and $\overline{T_8}$ dominate in Eq. (8), i.e., (i) the magnitude of each of these terms is much larger than the magnitude of another term in Eq. (8) and (ii) the positive sign of terms $\overline{T_5}$ and $\overline{T_8}$ is opposite to the negative sign of terms $\overline{T_6}$ and $\overline{T_7}$ so that $|\overline{T_5} + \overline{T_6} + \overline{T_7} + \overline{T_8}| \ll \min\{|\overline{T_5}|, |\overline{T_6}|, |\overline{T_7}|, |\overline{T_8}|\}$ in the largest part of the mean

flame brush. Thus, Fig. 2 implies that the use of a separate closure relation for each term on the RHS of Eq. (8) may result in a large error in $\overline{T}_\Sigma$ due to small errors inherent to any model closure relation.

Fig. 2. Various terms on the RHS of Eq. (8), normalized using ρ_u , S_L , and δ_{th} .

Figure 3 shows that the joint closure relation given by Eq. (17) yields encouraging results for all three Lewis numbers. In particular, at low values of $\bar{c}$, the approach predicts a significant increase in $\overline{T}_\Sigma$ with decreasing Le . Moreover, the approach predicts $\overline{T}_\Sigma(\bar{c})$ at $Le = 0.8$ and 0.6 , as well as at $\bar{c} \leq 0.3$ and $Le = 0.34$. At larger values of $\bar{c}$ and $Le = 0.34$, the joint closure relation overestimates $\overline{T}_\Sigma(\bar{c})$, probably, due to the neglect of the unsteady term on the RHS of Eq. (14) or an increase in the probability of finding negatively curved (and negatively stretched) reaction zones with increasing $\bar{c}$. Since the present analysis of stretched laminar flames has yet been restricted to planar or positively curved flames, the linear relation given by Eq. (15) may not hold if the flame is negatively curved. This issue will be addressed in future work. Nevertheless, results reported in Fig. 3 appear to be promising bearing in mind the lack of any tuning parameter in Eq. (17). It is also worth remembering that Eq. (17) was earlier validated [20,21] against three other DNS databases computed by two independent research groups under substantially different conditions, but at $Le = 1$.

Figure 4 shows normalized profiles of $\langle \dot{s} \rangle_W = \overline{\rho W \dot{s}} / \overline{\rho W}$, obtained for various Le using $S_{d,\theta}$. This figure implies that the increase in $\overline{T}_\Sigma$ at low $\bar{c}$ with decreasing Le , shown in Fig. 3, stems from an increase in the conditioned stretch rate. The

increase in $\langle \dot{s} \rangle_W$ ($\bar{c} \ll 1$) stems from the fact that a flame characterized by a lower Le can survive under the influence of a higher stretch rate, with all other things being equal, e.g., cf. numbers on the abscissa axes in Figs. 1a, 1b, and 1c. For purely geometrical reasoning, positively curved reaction zones dominate at low $\bar{c}$, with the highest possible value of the local curvature being increased with decreasing Le , thus, making $\langle \dot{s} \rangle_W$ larger.

Fig. 3. Validation of Eq. (17). Dashed and dotted-dashed lines show results obtained using S_d and $S_{d,\theta}$ when evaluating the stretch rate.

Fig. 4. Profiles of the conditioned stretch rates, obtained for various Le and normalized using S_L and δ_{th} .

Moreover, Eq. (17) and Fig. 4 provide a clue to understanding why the leading edge of a premixed turbulent flame brush can control the flame speed S_L , as hypothesized within the framework of the leading point concept put forward by Zeldovich

[12]. The concept is discussed in details elsewhere [1-3], with the body of evidences in favor of it has been growing over the past years [9-11,37-40]. Indeed, if the turbulent flux $\overline{\rho \mathbf{u}'' \tilde{W}''}$ is weak when compared to the mean flux $\bar{\rho} \tilde{u} \tilde{W}$, as shown recently [22], then, for qualitative discussion, Eq. (17) may be simplified as follows

$$\rho_u S_t \frac{d\tilde{W}}{dx} = \bar{\rho} \tilde{W} \langle \dot{s} \rangle_W \quad (18)$$

for a flame that moves from right to left in a statistically 1D planar fully-developed case. The form of this equation and Fig. 4 implies that the mean rate $\tilde{W}$ is increased with x at low $\bar{c}$, where $\langle \dot{s} \rangle_W > 0$, but is decreased with x at large $\bar{c}$, where $\langle \dot{s} \rangle_W < 0$. Accordingly, $\rho_u S_t = \int_{-\infty}^{\infty} \bar{\rho} \tilde{W} dx$, i.e., the area under a curve of $\bar{\rho} \tilde{W}(x)$, is strongly affected by the slope $d\tilde{W}/dx$ at low $\bar{c}$. The larger the slope, the larger the area and, hence, the larger S_t . Consequently, S_t is increased by the conditioned stretch rate $\langle \dot{s} \rangle_W$ evaluated near the leading edge.

For instance, if (i) the dependence of $\bar{\rho} \tilde{W}$ on $\bar{c}$ has a dome-like shape, e.g., $\bar{\rho} \tilde{W} \propto \rho_u \bar{c}(1 - \bar{c})$ [41], and (ii) $\bar{c}$ is approximated as $\bar{c} = [1 + \exp(4x/\delta_t)]^{-1}$ [3,42,43], where δ_t is the mean flame brush thickness, then, $\rho_u S_t d\tilde{W}/dx \propto \rho_u S_t (1 - 2\bar{c}) d\bar{c}/dx = \rho_u S_t (1 - 2\bar{c}) \bar{c}(1 - \bar{c})/\delta_t \propto (1 - 2\bar{c})(S_t/\delta_t) \bar{\rho} \tilde{W}$ and Eq. (18) implies that $S_t \propto \delta_t \langle \dot{s} \rangle_W (\bar{c} \rightarrow 0)$, i.e., the turbulent flame speed is controlled by the conditioned stretch rate at the flame leading edge. Thus, Fig. 4 and Eq. (18) explain the aforementioned strong increase in the computed values of S_t/S_L with decreasing Le ($S_t/S_L = 2.5, 4.6$, and 13.7 at $Le = 0.8, 0.6$, and 0.34 , respectively [29]). Moreover, Eq. (18) implies that modeling of the behavior of the product $\bar{\rho} \tilde{W} \langle \dot{s} \rangle_W$ at low $\bar{c}$ is of paramount fundamental importance and this will be a subject for future study.

6. Conclusions

Transport equations for the rate W of product creation and its Favre-averaged value $\tilde{W}$ were derived by considering a premixed turbulent flame characterized by the Lewis number different from unity. Subsequently, based on theoretical and numerical investigations of variously stretched laminar flames characterized by $Le < 1$, a simple joint closure relation for the sum of all seven unclosed terms on the RHS of the equation for $\tilde{W}$ was developed, see Eq. (17). While Eq. (17) does not solve the problem of closing the RHS of the transport equation for $\tilde{W}$, as the conditioned stretch rate $\langle \dot{s} \rangle_W$ still requires modeling, the proposed joint closure relation appears to be the key step to solve the problem, as a sum of seven unclosed terms, which counterbalance one another almost completely, is reduced to a single term.

The joint closure relation was assessed by analysing 3D DNS data obtained from three statistically 1D, planar, adiabatic, premixed turbulent flames in the case of a single-step chemistry and $Le = 0.34, 0.6$, or 0.8 . The obtained agreement between the model and DNS results is promising, thus, indicating that the sum $\bar{T}_\Sigma$ of seven unclosed terms on the RHS of Eq. (8), some of them counterbalance one another almost completely, may be modelled with a single term $\bar{\rho} \tilde{W} \langle \dot{s} \rangle_W$. Assessment of this hypothesis at various Re_t or Ka and for different flame configurations is necessary for further validation.
