A global analysis recently showed that seabird breeding phenology (as the timing of egg-laying and hatching) does not, on average, respond to temperature changes or advance with time (Keoghan et al. 2018 Nat. Clim. Change 8, 313–318). This group, the most threatened of all birds, is therefore prone to spatio-temporal mismatches with their food resources. Yet, other aspects of the breeding phenology may also have a marked influence on breeding success, such as the arrival date of adults at the breeding site following winter migration. Here, we used a large tracking dataset of two congeneric seabirds breeding in 14 colonies across 18° latitudes, to show that arrival date at the colony was highly variable between colonies and species (ranging 80 days) and advanced 1.4 days/year while timing of egg-laying remained unchanged, resulting in an increasing pre-laying duration between 2009 and 2018. Thus, we demonstrate that potentially not all components of seabird breeding phenology are insensitive to changing environmental conditions.

1. Introduction

Timing of life-history events such as reproduction is predicted to have evolved to optimally use temporally favourable conditions in seasonal systems [1]. Breeding phenology is a key adaptation with direct consequences on reproductive success and population dynamics [2,3]. Rapid climate change has led to an
advancement of the annual cycle in many organisms in temperate and polar regions, while species that have not adjusted to climate change seem to be more prone to population declines [4,5]. In seabirds, the timing of egg-laying has been shown to be insensitive to changing climatic conditions globally, highlighting the vulnerability of this group to mismatches with lower-trophic-level resources [6]. Yet, spring arrival at the colony, and the pre-laying period—the time between arrival at the colony and egg-laying— are also important and rarely considered components affecting breeding success. This period allows birds to establish and defend nest sites [7], build up body condition [8,9] and mate [10], which often starts months before egg-laying [11,12].

Here, we took advantage of a large tracking dataset, enabling us to determine arrival dates in two seabird species, across 9 years (2009–2018) and 14 colonies across a large latitudinal gradient (62°N–79°N), to test if arrival date does not exhibit any trend across years, similar to the timing of egg-laying [6]. These data were available for two colonial, congeneric species, the common (hereafter COGU, Uria aalge) and Brünnich’s guillemot (hereafter BRGU, Uria lomvia). These species are long-distance migrants [13–15], have similar morphology and life history [16,17], and exhibit no trend in breeding phenology [18], but contrasting population trends [19–21]. Their arrival date is hypothesized to be driven by the timing of food availability in the vicinity of the colony [22,23], which can be roughly approximated by latitude [24], or by colony size through increasing pressure on nest site defence displayed as longer pre-laying periods in larger colonies [11,25,26]. We tested the hypothesis that the arrival date is without trend across years, similar to the egg-laying date. Furthermore, we examined if arrival date is delayed with latitude, similar to the timing of egg-laying [24], or determined by colony size due to pressure on nest site defence.

2. Material and methods

(a) Data acquisition

The date of first arrival at the colony for each colony and species was estimated using salt water immersion data recorded by light-level geolocators deployed on adult breeders. The arrival date was here defined as the date when the pre-laying period commences. It was identified as the date when the majority of tracked individuals attended the colony for the first time after the non-breeding period, using the assumption that first arrival back at the colony is synchronized and independent of sex in guillemots [26–28] (details in the electronic supplementary material). Using a colony-wide first arrival date rather than individual arrival dates resulted in more robust results due to limitations in logger data resolution and accuracy. Tracking data were available from 14 colonies (figure 1a), for 1–8 years (in the period 2009–2018) [29]. BRGU and COGU breed sympatrically at five of these colonies. Three instances of estimated arrival dates could be validated with available time-lapse camera data at two colonies (electronic supplementary material, figure S1). To estimate pre-laying duration as well as temporal changes in phenology, we...
gathered annual measures of breeding timing which were available as population-level mean hatching dates at 12 colonies (details in the electronic supplementary material) for 1–7 years (in the period 2009–2018) [24,30–37]. To assess the potential consequences of variable arrival dates on reproductive success, we used annual breeding success for which data were available from five colonies (details in the electronic supplementary material) for 4–6 years (in the period 2010–2017) [30–37].

(b) Data analysis

(i) Temporal trends in breeding phenology and their consequences

Colony- and species-specific inter-annual variation in arrival dates was quantified as standard deviation (SD) from mean arrival timing. To test if arrival date changes with year, we applied a linear mixed-effect model (LME, package lme4) with relative arrival dates (mean = 0) as response variable (n = 79), year and species as fixed effects and id (as combination of colony and species) as random intercept. The same model was applied on a subset of data for which mean hatching date data were available (n = 40). Using this subset, we applied the same fixed and random effects to relative pre-laying duration as well as relative mean hatching date as response variables in order to assess if guillemot hatching timing and pre-laying duration have changed over time. Most parsimonious models were selected using the Akaike information criterion [38], resulting in all instances in removal of species and its interaction with year as predictor variables. We calculated the percentage of variance explained by the fixed effects (marginal R²) and fixed and random effects (conditional R²) [39]. In order to assess if a large-scale factor is driving temporal trends in arrival date, we assessed temporal synchrony as mean correlation of relative arrival dates between colonies using the msynch function (package ade4 [40]). To test if potential temporal trends in arrival date had an effect on reproductive output, we applied an LME with standardized breeding success (SD = 1, mean = 0) as response variable, relative arrival date as fixed effect and id as random intercept (n = 33).

(ii) Effect of latitude and colony size on arrival date

To test for the effect of latitude on arrival date at the colony, we applied a linear model with mean species- and colony-specific arrival date as the response variable (n = 19) and latitude and species and their interaction as predictors. Furthermore, if latitude drives arrival date, we would expect that colonies close to each other would exhibit similar arrival timing. Hence, we used a Mantel correlation test with 1000 permutations (package ade4) to test if spatial proximity can explain the mean arrival date in either species. Alternatively, to test if arrival date and consequently pre-laying duration can be instead linked to colony size, we applied a linear model with mean species- and colony-specific pre-laying duration as the response variable (n = 15) and colony size on the log-scale and species as predictors. Population counts are taken from a similar time period to account for the contrasting population trends (electronic supplementary material, table S1). To account for collinearity, we also tested latitude against colony size, but found no overall latitudinal trend (linear model,  = −0.10 with standard error (SE) = 0.10, adj. R² ≤ −0.01). R (v. 3.5.1, [41]) was used for all statistical analyses.

3. Results

(a) Timing of colony arrival

Annual arrival dates varied between 28 January and 18 April with considerable variation across the Northeast Atlantic (figure 1b). Most of this variation is found among colonies (SD = 21.6 and 16.2 days for COGU and BRGU, respectively, electronic supplementary material, figure S1) and species (SD = 12.8 days across sympatric colonies), while colony- and species-specific inter-annual variation was significantly smaller (mean SD = 7.8 and 4.9 days for COGU and BRGU, respectively).

(b) Temporal variability in breeding phenology and its consequences

Timing of hatching in guillemots showed no trend over time ( = −0.17 with SE = 0.23, marg. R² = 0.01, cond. R² = 0.01; figure 2c). By contrast, arrival date at the colony advanced by 1.4 days/year irrespective of species (full dataset:  = −1.4 with SE = 0.28, marg. R² = 0.24, cond. R² = 0.24; subset with available mean hatching data:  = −1.7 with SE = 0.35, marg. R² = 0.39, cond. R² = 0.39; figure 2a). This was also visible as prolonged pre-laying duration ( = 1.4 with SE = 0.40, marg. R² = 0.23, cond. R² = 0.23; figure 2b) as arrival date and pre-laying duration were highly and negatively correlated (−0.86). Colony arrival dates did not display synchrony among each other for either species (COGU: mean correlation = 0.15 with 95% confidence interval (CI) = −0.34–0.55 and BRGU: 0.09 with CI = −0.56–0.71). No consequence of an advancing arrival date was detectable in exhibited breeding success for either species ( = −0.005 with SE = 0.02, marg. R² = < 0.01, cond. R² = < 0.01; figure 2d).

(c) Does latitude or colony size predict the arrival date?

Mean arrival date at the colony could not be explained by latitude and the two species exhibited opposite trends ( = 1.63 with SE = 1.24 and  = −2.73 with SE = 2.19, adj. R² = 0.23; figure 1b). Similarly, there was weak evidence for an effect of proximity on arrival dates for COGUs (Mantel correlation = 0.19, p = 0.14), but somewhat stronger evidence in BRGUs (Mantel correlation = 0.29, p = 0.034). Contrastingly, pre-laying duration showed substantial variability among colonies (mean = 75 days, SD = 19, range = 49–102) and was highly correlated with colony size ( = 6.96 with SE = 0.97, adj. R² = 0.82; figure 1c).

4. Discussion

The main findings of our study are that timing of first arrival at the colony of both guillemot species and all colonies was highly variable and advanced through time despite no visible trend in mean hatching date. This advancement had apparently no effect on guillemot average breeding success. Furthermore, the duration of the pre-laying period and hence timing of arrival is not determined by latitude, but is better explained by the size of the colony, being longer in large colonies.

Theoretically, the minimum pre-laying duration required in guillemots is 5 days, as females undertake a 4 day long pre-laying exodus away from the colony [42]. Yolk formation (usually 14–15 days [42]) could also occur away from the colony and fertilization occurs very soon after ovulation, which in turn occurs 24 h before the egg is laid [10]. So, copulation right before the pre-laying exodus should be sufficient. Nonetheless, here we identified extensive pre-laying periods of more than one and up to several months with large variability between colonies and species. In an extreme case of a population further south, most breeding birds arrive back.
This variability may have costs and benefits associated with it. During the pre-laying period, prospective breeders attend the colonies at regular intervals [26–28] which restricts them to quasi-central place foraging. This, in turn, limits their available prey options and could even lead to local depletion of food resources before spring bloom at large colonies [44], decreasing their body condition and potentially breeding probability prior to breeding. Alternatively, early return to the breeding sites might help secure nesting sites, mating partners, and facilitate courtship [23], or it might be a response to unfavourable conditions experienced by these migrants during the end of their non-breeding period, resulting in an earlier return to the colony.

We showed that colony arrival date advanced in both the Brünnich’s and common guillemot across the study area, while their timing of hatching did not display any trend as shown previously in seabirds globally [6] and for alcids in the Atlantic and Pacific [18]. Contrary to these previous studies, concluding that breeding phenology is insensitive to short-term climatic change, we identified a clear trend in arrival dates across both species studied. This advancement resulted in an increasing pre-laying duration as mean hatching date did not advance, suggesting that part of breeding in these seabirds is indeed sensitive to changing conditions, although we cannot derive conclusions regarding the process driving this phenomenon or if it is an adaption to a changing environment. A potential explanation could be that the cue used to time arrival across the North Atlantic is changing as has been shown in some passerine species [45], but could not be demonstrated in others [46,47].

Although overall timing in both species exhibits the same trend, arrival time series were not synchronized between species and colonies. This indicates that short-term fluctuations in arrival date were not parallel through time among species and/or colonies, which suggests the interaction between large-scale environmental trends acting on the entire species combined with more local features. However, environmental conditions, although exhibiting the same trend, do not change homogeneously across the genus’ range [48], which encompasses most of the North Atlantic for these species breeding within the study area [13–15]. Hence, synchrony is not necessarily expected. As of now, we could not detect any immediate consequences of advancing arrival dates on population-wide reproductive success. As we used adult breeders to estimate arrival times, we cannot make any inference of the potential effect of advancing arrival dates on breeding propensity. Not all birds breed every year [49,50] and the egg laying and hatching dates as well as the recorded breeding success may reflect only individuals with sufficient body condition, i.e. the ones that managed to get enough energy during the pre-laying period in order to breed [8].

Pre-laying duration and hence arrival timing at the colony could be linked with colony size [11,25,26] rather than latitude. This could explain the displayed large-scale variability in arrival timings between colonies as well as the lack of synchronicity between time series. Although guillemots typically show high nest site fidelity, site changes are documented which usually increase nest site quality for the usurper and decrease it for the usurped [51] underlining the importance of nest site defence as a potential driver of arrival date resulting in the pressure to arrive earlier in larger colonies [11,25,26]. But, the influence of environmental conditions on arrival timing cannot be ruled out, as unfavourable weather has already been shown to affect pre-laying colony attendance in BRGU [27] although the same could not yet be shown for arrival timing.

Figure 2. Temporal trends in arrival dates at the colony (a), pre-laying duration (b) and mean hatching date (c). The dashed line in (a) represents linear mixed-effect model predictions for the subset of data for which hatching timing information was available (squares), while the solid line in (a) illustrates the same model prediction for arrival date using the entire dataset (squares and dots). (d) The relationship between advancing arrival date and breeding success. Bands in all panels indicate bootstrapped 95% CIs for predicted values calculated using the bootMer function with 1000 simulations (package lme4). Red and blue symbols represent COGU and BRGU, respectively.

at the colony already in the autumn and in at least some years birds attend the breeding sites throughout the winter [11,43].
Our large-scale approach highlights the extent and importance of the pre-laying period in contributing to the challenges faced by colonial breeders in a changing environment. The advancing trend in arrival dates elucidates that not all parts of breeding phenology in seabirds are insensitive to change across years, although we cannot make inferences if this change is adaptive or not.

Ethics.
