Abstract: We demonstrate a novel energy-efficient method for seeding CEP-stable OPCPAs. We couple the CEP-stable idler of a broadband OPCPA into a Kagome fiber thus compensating for its angular chirp. We show the pulse compressibility.

OCIS codes: 190.4970 Parametric oscillators and amplifiers; 060.4005 Microstructured fibers

The quest for isolated attosecond pulses (IAPs) in the water window drives the research of carrier-envelope phase (CEP) stable high-energy, short-pulse sources in the infrared. The spectral region around 2- μm is a good compromise between high harmonic generation (HHG) efficiency and cut-off extension for reaching the water window spectral region. To produce few-cycle pulses at 2- μm , necessary for driving IAPs, the preferred optical scheme consists in pumping optical parametric chirped pulse amplifiers (OPCPAs) with 1- μm lasers. One difficulty of this approach is the generation of a few-cycle CEP-stable seed starting from a non-CEP-stable laser. Degenerate optical parametric amplifiers (OPAs) or OPCPAs with type-I β -barium borate (BBO) crystals are able to produce few-cycle signal and idler pulses, in which the idler has a stable CEP [1]. Such broadband OP(CP)As can be generated either collinearly or non-collinearly. In a collinear setup, the idler is angular-chirp free, it is spatially overlapped with the signal, has the same spectral content and the same polarization, but a different CEP. Therefore it is not possible to spatially separate the CEP-stable idler from the non-CEP-stable signal beam. In a non-collinear setup, the idler has a very strong angular chirp due to different phase matching for each signal-idler wavelength pair. In both cases, the idler cannot be used as a seed for successive amplification stages. An optical design [2,3] was introduced to address this problem, consisting in using a narrowband collinear or non-collinear OP(CP)A with signal and idler at different spectral regions with a negligible angular chirp compared with the natural beam divergence of the idler. The CEP-stable idler or its second harmonic then pumps a CEP-stable broadband supercontinuum which can be used as a seed for successive amplification stages. This method was used in several works and it is of great advantage in particular for optical parametric synthesizers due to the possibility to produce a CEP-stable seed over multiple octaves [4,5].

In this work, we introduce a novel scheme which allows saving pump energy for the generation of a few-cycle CEP-stable seed for a single channel OPCPA chain. The method consists in using a broadband non-collinear OPCPA with a strongly angularly-chirped idler and focusing it into a Kagome fiber [6]. The Kagome fiber is used in a linear regime and it homogenizes the wave-vector directions of all idler wavelengths, similarly to the technique used for homogenizing diode lasers [7]. At the output of the fiber, the CEP-stable broadband idler has a well-defined propagation direction, i.e. no angular chirp, and can be directly used to seed the following amplification stages. We believe that our technique is simpler than other techniques developed to compensate for the idler angular chirp of an OPA [8,9].

In our setup (Fig. 1a) we utilized 308 μJ of total pump energy from the same home-built Yb:KYW regenerative amplifier [10] used in [5] and built a 2-stage degenerate OPCPA with BBO crystals. The idler output energy of the second OPCPA stage is 10.6 μJ and it has a strong angular chirp which we measured to be $\sim 3.6^\circ$. We focused the idler into a Kagome fiber with $\sim 22\text{-cm}$ length (7-cell core design with 63 core diameter). The fiber output energy is 3.8 μJ , which can be further improved by optimizing the coupling efficiency (currently 36%) into the Kagome fiber. The spectra of the idler before and after the Kagome fiber are shown in Fig. 1 (b). The fiber output has no residual detectable angular chirp.

Fig. 1. (a) Optical layout. A 10-mm YAG was used for white light generation (WLG), and 2 consecutive 4-mm BBO crystals were used for the 2 OPA stages (b) Spectra of the idler of the second OPA stage before and after the Kagome fiber.

To demonstrate the temporal compressibility of our pulses, we performed second harmonic generation frequency resolved optical gating (SHG FROG) measurements and retrieved 60-fs pulse duration. As shown in Fig. 2, the retrieved phase is smooth and we expect that it can be easily compressed to 30-fs transform limit.

Fig. 2. Measured (a) and retrieved (b) FROG traces; (c) measured (green) and retrieved (blue) spectral intensity; retrieved spectral phase (orange); (d) retrieved temporal intensity (blue) and phase (orange).
