Received: date / Accepted: date

Abstract The present work compares two different drag breakdown methods based on the wake survey of a finite size wing. The traditionnal control volume approach based on a global balance of momentum (cf. for instance [17]) is considered, and compared to the phenomenological drag breakdown formulation put forward by Méheut & Bailly [14] within the aerodynamic context. Both formulations require information on the velocity field, but also the static or stagnation pressure in the wake plane of the model of interest. In this paper, we focus on computing the results based on velocity data exclusively, acquired by stereo-PIV. These two methods are benchmarked experimentally on the wake of a SACCON [19] model, that has been measured in one of ONERA's wind-tunnels, and their performance is evaluated by comparing their results to direct force balance measurements. It is shown that while both methods perform similarly, with drag predictions lying within 10% of the balance measurements, the control volume approach systematically underestimates the total drag. This behavior is attributed to the PIV-reconstructed pressure field failing in capturing the high depression occurring in the cores of the

strong tip vortex. We also discuss how the phenomenological approach can inform on the physical origins of drag, thereby giving aerodynamicists valuable clues as to how to fine-tune the performances of a given airframe.

1 Introduction

In a world increasingly concerned with energy and cost savings, it has become critical for aerodynamicists to accurately measure and predict the effects of drag acting on air vehicles. This task is all the more difficult, as drag may result from drastically different physical phenomena, ranging from viscous skin friction to shock waves, via the mere presence of lift. The mandatory first step towards improving the efficiency of an airframe is thus to accurately describe and measure these various drag components. The direct measurement of total mean drag acting on a model using force balances has been tried and tested, and is nowadays customarily found on industrial and research experimental platforms. Though reliable, this method only gives a global assessment of drag, and makes it impossible to distinguish between its various sources.

This drawback may be bypassed by expressing the total aerodynamic force in terms of the surrounding flow's properties, by means of a global balance of momentum. The main difficulty associated with the aforementioned method then comes from accurately evaluating the pressure and velocity fields throughout a control volume, which can sometimes be quite large. Within this context, Particle Image Velocimetry (PIV) appears to be a measurement method particularly well suited

for this task, as it can yield velocity fields throughout large domains. And indeed, Van Oudheusden *et al.* [24] [25] demonstrated that the control volume approach fed exclusively with planar PIV data was viable when considering the mean aerodynamic loads acting on a two-dimensional (2D) airfoil. Since then, the continuous improvements made to PIV whether in terms of accessing the out of plane velocity component, or increasing spatial and temporal resolutions have made it possible to infer ever more precisely the relationship between the forces acting on an object, and its surrounding flow. For instance, Ragni *et al.* [15] [16], computed the time and phase averaged loads acting on straightly flying and rotating airfoils respectively. The lift was computed by integrating the pressure coefficient along the airfoil's contour, which had been determined beforehand by integrating the Navier-Stokes equations fed with stereo-PIV data. Drag, on the other hand, was deduced from PIV measurements of the momentum deficit in the wake. These PIV based loads were reported to be within 10% of those measured using conventional methods (pressure taps and pitot probes). Alternately, Unal *et al.* [22], Kurtulus *et al.* [10], David *et al.* [5] and Villegas & Diez [27] took advantage of time resolved planar PIV data to examine the relationship between the instantaneous loads acting on 2D profiles and the unsteady surrounding flow, and studied the drag in terms of convective, pressure and turbulent contributions. In particular, these studies enabled to associate periodic features of the loads and vortex shedding in the wake. More recently, Terra *et al.* [20], [21] have estimated the drag acting on bluff bodies, based on the investigation of their wakes with large scale tomographic PIV. Notably, the former study investigates the drag acting on a sphere towed across quiescent air, and highlights the competition between the convective and pressure contributions to drag, as a function of the distance between the investigation plane and the model.

The control volume approach in the form discussed above still entangles the different drag components resulting from irreversible losses of energy (i.e. viscous, form and wave drag, which add up to profile drag), to those resulting from the presence of lift (i.e. induced drag). To illustrate this point, let us consider the wake vortices that typically appear at the edges of three-dimensional wings, which result from a sudden pressure discrepancy at the crossing of the wing-tip. This sharp pressure gradient ultimately drives a strong cross-flow around the wingtip, whose magnitude can reach, in the present study, up to 20% of the streamwise velocity component. In the process of setting up wake vortices around its body, the airframe loses energy in the form of induced drag. It is however impossible

to attribute the overall induced drag production to either inertia or pressure alone, since both effects contribute to the phenomenon. Within this context, the work of Jone's [9] can be seen as a first attempt to extract the profile drag resulting from viscous and form drag only, by considering the momentum deficit in the wake of two-dimensional (2D) airfoils flying through an incompressible fluid. This approach was further extended by Maskell [13] and Cummings *et al.* [4], who presented a way to determine lift induced drag. They did so by accounting for the presence of a transverse flow in the downstream plane, and showed that the induced drag in fact simply boiled down to the integration of the transverse kinetic energy at that same location. Finally, Destarac *et al.* [7] and Kusunose *et al.* [11] extended the latter methods to the compressible flow regime, where profile drag may also be generated by the emergence of shock waves upon the model. In such regimes, it is helpful to link profile drag to the production of entropy. In particular, the latter authors put forward a wave drag extraction method, based on the observation that the profile drag resulting from viscous shear layers is rotational (hence can be determined from Crocco's theorem), whereas the profile drag resulting from shock waves occurs in irrotational regions of the wake (hence wave drag can be calculated from the Rankine-Hugoniot shock jump formula).

The goal of the present work is to compare the performances of both approaches in an experimental context, where measurements stem from PIV. For the sake of simplicity, the framework adopted here will focus on the incompressible regime. We will start by reviewing the mechanical and phenomenological drag breakdown methods in section 2. The experimental rig used for the present investigation will then be described in section 3, while the implementation and robustness of both methods will be assessed in section 4. Global drag results will eventually be presented and discussed in section 5.

2 Theoretical background

2.1 Mechanical drag breakdown

Let us consider an aircraft model immersed in an upstream uniform flow $U_\infty \mathbf{e}_x$ of density ρ and dynamic viscosity μ . The cornerstone of the method consists in performing a global balance of momentum over the control volume $\mathcal{V}$ of contour $\partial\mathcal{V}$ and outwards pointing normal $\mathbf{n}$, which is fully encompassing a model of wing area S_{ref} (cf. Fig. 1). Considering a steady mean flow and time averaged quantities, the mean aerodynamic

Fig. 1 Control volume of interest. The region enclosed in the dashed loop is referred to as the wake w , which is a subset of the downstream plane S_1 . Outside of this region, the profile drag, induced drag and turbulent contributions have completely vanished, unlike those associated to the convective and pressure terms.

load $\mathbf{F}$ acting on the model is traditionally found to be

$$\mathbf{F} = - \int_{\partial V} \rho (\mathbf{U} \cdot \mathbf{n}) \mathbf{U} dS - \int_{\partial V} \rho \langle \mathbf{u}' \otimes \mathbf{u}' \rangle \cdot \mathbf{n} dS - \int_{\partial V} P \mathbf{n} dS + \mu \int_{\partial V} [\nabla \mathbf{U} + (\nabla \mathbf{U})^T] \cdot \mathbf{n} dS, \quad (1)$$

where $\mathbf{U} = U \mathbf{e}_x + V \mathbf{e}_y + W \mathbf{e}_z$ and P respectively represent the mean velocity and mean static pressure fields. The term $\langle \mathbf{u}' \otimes \mathbf{u}' \rangle$ refers to the Reynolds stress tensor, with $\mathbf{u}' = u' \mathbf{e}_x + v' \mathbf{e}_y + w' \mathbf{e}_z$ being the turbulent velocity fluctuation. The effects of viscous friction along ∂V are considerably smaller than any other term (about two orders of magnitude here), hence can be safely dropped. Assuming that the lateral boundaries are sufficiently far from the model, there is no flux of momentum across them, and the global balance simplifies to evaluating the difference of momentum between the up- and downstream planes of the control volume S_∞ and S_1 respectively. This assumption also implies that the turbulent stresses will be non negligible only in the downstream plane S_1 . Further invoking the conservation of mass, and the fact that integrating P_∞ over the closed contour ∂V is zero, the total drag coefficient $C_D = 2 \mathbf{F} \cdot \mathbf{e}_x / \rho_\infty S_{\text{ref}} U_\infty^2$ can be expressed in terms of a surface integral over the downstream plane S_1 of the control volume, and reads

$$C_D = \frac{2}{S_{\text{ref}}} \int_{S_1} \left[\frac{\rho}{\rho_\infty} \frac{U}{U_\infty} \left(1 - \frac{U}{U_\infty} \right) + \frac{P_\infty - P}{\rho_\infty U_\infty^2} - \frac{\rho}{\rho_\infty} \frac{\langle u' u' \rangle}{U_\infty^2} \right] dS. \quad (2)$$

In the above, subscript ‘ ∞ ’ refers to the uniform free-stream quantities. Eq. 2 gives a mechanical description of the production of drag, by associating it to the properties of the flow (namely convection, pressure and turbulent stresses), which concurrently take part in all the

various drag sources. The mechanical drag breakdown C_D^{Mec} ensues, and may be written as

$$C_D^{\text{Mec}} = C_D^{\text{Conv}} + C_D^{\text{Press}} + C_D^{\text{Turb}}, \quad (3)$$

where

$$C_D^{\text{Conv}} = \frac{2}{S_{\text{ref}}} \int_{S_1} \frac{\rho}{\rho_\infty} \frac{U}{U_\infty} \left(1 - \frac{U}{U_\infty} \right) dS, \quad (4)$$

$$C_D^{\text{Press}} = \frac{2}{S_{\text{ref}}} \int_{S_1} \frac{P_\infty - P}{\rho_\infty U_\infty^2} dS, \quad (5)$$

and

$$C_D^{\text{Turb}} = - \frac{2}{S_{\text{ref}}} \int_{S_1} \frac{\rho}{\rho_\infty} \frac{\langle u' u' \rangle}{U_\infty^2} dS. \quad (6)$$

According to this formulation, a sufficiently large plane S_1 must be considered, in order to compute a precise estimate of the total mean drag acting upon the model.

2.2 Phenomenological drag breakdown

Since the seminal work of Betz [1], numerous phenomenological drag breakdown methods have been put forward, many of which are reviewed and compared in Méheut & Bailly [14]. We focus in this paper on the phenomenological drag breakdown put forward by the latter authors, which gives a complete drag breakdown, whose integration is reduced to the sole wake.

The cornerstone of Méheut and Bailly’s phenomenological drag breakdown is Eq. 2. Unlike them however, we keep the Reynolds stress term, which is fully accessible using stereo-PIV data. (Neglecting turbulent stresses was required when wake data was measured with five-hole and Pitot probes, which only gave access to mean velocity fields.) Eq. 2 is then specialized to the aerodynamic case by expressing the ratio of fluid densities using the perfect gas constitutive law, in which the stagnation pressure P_i and temperature T_i are introduced. The flow is supposed to be isenthalpic (i.e. there are no heat sources), such that the stagnation temperature remains constant and equal to its freestream value everywhere. Finally, the downstream plane is assumed to be located sufficiently far away from the model, such that the quantities measured downstream differ only slightly from those upstream. Within this small perturbation framework, one can define $P_i = P_{i\infty} + \delta P_i$ ($P_{i\infty}$ being the freestream stagnation pressure) and $\mathbf{U} = (U_\infty + \delta u) \mathbf{e}_x + \delta v \mathbf{e}_y + \delta w \mathbf{e}_z$, where the perturbations $\delta P_i / P_{i\infty}$, $\delta u / U_\infty$, $\delta v / U_\infty$ and $\delta w / U_\infty$ are all small compared to one. Owing to an asymptotic expansion up to

second order, Méheut & Bailly showed that Eq. 2 could be re-written in the form

$$C_D = \frac{1}{S_{\text{ref}}} \int_w \left[-\frac{2}{\gamma M_\infty^2} \frac{\delta P_i}{P_{i\infty}} + (M_\infty^2 - 1) \frac{\delta u^2}{U_\infty^2} \right] dS \\ + \frac{1}{S_{\text{ref}}} \int_{S_1} \frac{\delta v^2 + \delta w^2}{U_\infty^2} dS \\ - \frac{2}{S_{\text{ref}}} \int_{S_1} \frac{\rho}{\rho_\infty} \frac{\langle u'u' \rangle}{U_\infty^2} dS, \quad (7)$$

where γ represents the heat capacity ratio, and $Ma_\infty = U_\infty/\sqrt{\gamma r T_\infty}$ is the freestream Mach number ($r = 287$ J/kg/K being the specific gas constant for air). The equation above now has a strong physical meaning. Indeed, the latter authors showed that the first integral on the right hand side of Eq. 7 translated the irreversible losses of energy, and was thus attributable to profile drag. By contrast, the second integral on the right hand side of Eq. 7 is proportional to the transverse kinetic energy that has emerged downstream of the model. As such, it is representative of the induced drag resulting from trailing vortices. In addition, the works of Maskell [13] and Cummings *et al.* [4] showed that the integration domain of this second integral could be reduced to the wake only, by rewriting the transverse kinetic energy in terms of the streamwise vorticity component $\omega = (\nabla \times \mathbf{U}) \cdot \mathbf{e}_x$, and the 2D mean streamfunction $\psi = -(\partial_{yy}^2 \omega + \partial_{zz}^2 \omega)$ according to

$$\int_{S_1} \frac{\delta v^2 + \delta w^2}{U_\infty^2} dS = \int_w \frac{\psi \omega}{U_\infty^2} dS. \quad (8)$$

As one may notice, the longitudinal velocity gradients must be negligible in the wake plane for Eq. 8 to be valid, hence restricts the wake plane to be evaluated sufficiently far away from the model (typically no less than a chord away from the model). Finally, turbulent stresses naturally vanish outside of the wake since they originate from shear. It is therefore possible to reduce the integration domain of the third integral on the right hand side of Eq. 7 to the wake only, as well. In the end, the phenomenological total drag breakdown C_D^{Phen} reads

$$C_D^{\text{Phen}} = C_D^{\text{Prof}} + C_D^{\text{Ind}} + C_D^{\text{Turb}}, \quad (9)$$

where

$$C_D^{\text{Prof}} = \frac{1}{S_{\text{ref}}} \int_w \left[-\frac{2}{\gamma M_\infty^2} \frac{\delta P_i}{P_{i\infty}} + (M_\infty^2 - 1) \frac{\delta u^2}{U_\infty^2} \right] dS, \quad (10)$$

$$C_D^{\text{Ind}} = \frac{1}{S_{\text{ref}}} \int_w \frac{\psi \omega}{U_\infty^2} dS, \quad (11)$$

and

$$C_D^{\text{Turb}} = -\frac{2}{S_{\text{ref}}} \int_w \frac{\rho}{\rho_\infty} \frac{\langle u'u' \rangle}{U_\infty^2} dS. \quad (12)$$

As already stated, the integration domain of the phenomenological breakdown (9) is reduced to the actual wake w , while the control volume approach (3) requires an integration over the entire downstream plane S_1 (with the exception of C_D^{Turb} being in fact the same in both formulations). This particular feature of the phenomenological method makes it quite appealing experimentally speaking, as it drastically reduces the span of the domain to capture. There is however a trade-off with reducing the integration domain to the wake. Indeed, doing so focuses all the information scattered throughout space in a much smaller region, and especially in the viscous cores of the wake vortices. As a result, though the phenomenological method allows for smaller measurements domains, it requires a fine spatial resolution to accurately capture sharper velocity gradients.

2.3 Pressure calculation method

Inspecting Eqs. 5 and 10 above shows that the knowledge of both the static and stagnation pressure in the wake plane is required in order to evaluate drag using the mechanical and phenomenological approaches. Computing the pressure field from PIV velocity data, under the constraint of an incompressible flow is a long standing issue, which has received considerable attention in the past years [23], [17]. Note that in the more true to life case of a compressible flow, one may still compute the pressure field from velocity data, by invoking isentropic and isenthalpic relations, as put forward by Van Oudheusden *et al.* [25]. Owing to the low value of the free-stream Mach number $Ma_\infty = 0.10$, this particular study is restricted to the incompressible framework.

The pressure calculation strategy adopted here is based on the work of Jeon *et al.* [8], and relies on integrating the pressure gradient of the Navier-Stokes equations

$$-\nabla P = \rho [\mathbf{U} \cdot \nabla \mathbf{U} + \nabla \cdot \langle \mathbf{u}' \otimes \mathbf{u}' \rangle] - \mu \Delta \mathbf{U}. \quad (13)$$

The different terms composing the pressure gradient are calculated from the PIV measurements by spatial second order schemes. The pressure field is then obtained by minimizing a functional built on the difference of the

Fig. 2 Overview of the stereo-PIV setup: (i) Quantel Evergreen laser; (ii) Laser sheet. In order to discretize the axial gradients present in equation (13), three PIV planes have been subsequently shone at locations $x = c_{\text{ref}}$ (solid line), and $x = c_{\text{ref}} \pm \Delta x$ (dashed lines); (iii) 5.5 Mpixels LaVision Imager sCMOS cameras; (iv) Wake plane split into four $480 \times 300 \text{ mm}^2$ frames, with a 50 mm overlap.

pressure gradient based on the PIV measurements and the estimated pressure gradient, which is equivalent to solving a Poisson equation. The field is generally divided in sub-domains, based on the amplitude of the pressure gradient. The sequential pressure reconstruction is initiated from the outer domain, where the highest measurement accuracy is expected, hence where a reliable pressure reference can be taken. The pressure field in the other sub domains is then computed by imposing Dirichlet boundary conditions stemming from the previously computed outer domain.

Once the mean static pressure is reconstructed, the pressure integration constant P_{BC} is adjusted so that the average of the reconstructed pressure computed along the contour of the PIV domain coincides with the average of the static pressure computed from the isentropic relation

$$P_{BC} = P_{\infty} \left[1 + M_{\infty}^2 \frac{\gamma - 1}{2} \left(1 - \frac{\|\mathbf{U}\|^2}{U_{\infty}^2} \right) \right]^{\gamma/(\gamma-1)} \quad (14)$$

at the same location. The local stagnation pressure in the downstream plane eventually ensues from applying the local isentropic and isenthalpic relations to the previously determined local static pressure, following

$$P_i = P \left[\frac{1 + M_{\infty}^2 \frac{\gamma - 1}{2} \left(1 - \frac{\|\mathbf{U}\|^2}{U_{\infty}^2} \right)}{1 + M_{\infty}^2 \frac{\gamma - 1}{2}} \right]^{-\gamma/(\gamma-1)}.$$

3 Experimental apparatus and instrumentation

3.1 Wind-tunnel setup

This study was conducted on a model of the SACCON geometry, a generic flying wing configuration that was introduced within the framework of aircraft control and stability analyses [12] [26]. This particular configuration was chosen here as it is known to induce complex vortical patterns above its upper surface at medium and high angles of attack [18] [19]. It is therefore an excellent case study to try and test wake integral methods. The particular model used here has a wingspan $b = 1 \text{ m}$, a reference chord $c_{\text{ref}} = 0.31 \text{ m}$ and a reference area $S_{\text{ref}} = 0.3253 \text{ m}^2$. It was placed inside the L1 wind-tunnel of Lille's ONERA center, whose dodecagonal test-section is 2.4 m wide. The free-stream velocity was fixed at $U_{\infty} = 35 \text{ m/s}$ throughout the campaign, which corresponds to a free-stream Reynolds number $Re_{\infty} = \rho c_{\text{ref}} U_{\infty} / \mu = 1.1 \cdot 10^6$, and a free-stream Mach number $Ma_{\infty} = U_{\infty} / \sqrt{\gamma r T_{\infty}} = 0.10$. Three different angles of attack $\alpha = 9^\circ, 13^\circ$ and 18° were investigated. The wake was measured one chord away from the model's wingtips (cf. Fig. 2). The maximum blockage, which was encountered for $\alpha = 18^\circ$, did not exceed 2%, hence no particular correction was applied to the data.

Fig. 3 Mean flow field in the reference plane $x = c_{\text{ref}}$ for $\alpha = 9^\circ$ (left) and $\alpha = 18^\circ$ (right). The colormap outlines the longitudinal velocity component $U = \mathbf{U} \cdot \mathbf{e}_x$, while the vectors represent the transverse flow in the wake plane $\mathbf{U}_\perp = V\mathbf{e}_y + W\mathbf{e}_z$. The mean ratio of the transverse to longitudinal velocity $\|\mathbf{U}_\perp\|/U$ computed throughout the wake is indicated in the boxes.

Fig. 4 Magnitude of the normal turbulent stresses in the reference plane $x = c_{\text{ref}}$ for $\alpha = 9^\circ$ (left) and $\alpha = 18^\circ$ (right).

3.2 Measurement protocol

The stereo-PIV setup revolved around a dual cavity Nd:YAG Quantel Evergreen laser, which emitted at wavelength 532 nm with an output energy of 200 mJ per laser head, and two LaVision Imager sCMOS cameras with a 5.5 Mpixels resolution. The PIV images were processed using 32×32 pixels² interrogation windows, with an overlap of 50%, which resulted in velocity fields with a spatial resolution of 3 mm. Time averages were performed over 5000 consecutive snapshots acquired at 5 Hz in order to guarantee reliable statistics. Due to its large span, the wake was split into four 480×300 mm² overlapping PIV frames, with an overlap of 50 mm between adjacent frames. The cameras were fixed on a motor driven table that enabled a precise positioning of the different frames with respect to each other in space. In order to minimize the impact of edge effects when combining all frames together, the outer most frames were positioned such that they would contain the entire tip vortex. Finally, the longitudinal gradients present in

Eq. 13 were discretized by considering two additional planes, respectively located at $x = c_{\text{ref}} \pm \Delta x$, where $\Delta x = 30$ mm.

Subsequently to stereo-PIV measurements, the left half of the model's wake was surveyed using a five-hole probe. In order to reduce the acquisition time, the probe was mounted on a traversing system which swept across the wake at the constant speed of 5 mm/s. Data points were recorded every 2 mm, such that the characteristic traveling time τ_p of the probe between two measurements is $\tau_p = 0.4$ s. By comparison, the characteristic time of the flow τ_u is reasonably associated to the turnover time of the tip vortex following $\tau_u = \ell / \|\mathbf{U}_\perp\|$, where ℓ is the size of the tip vortex, and $\|\mathbf{U}_\perp\|$ the magnitude of the cross flow. Based on the data given in Fig. 3, $\tau_u \sim 0.03$ s, which is one order of magnitude smaller than τ_p . As a result, the five-hole probe experiences many turnover times during its travel time from one measuring point to another. It is therefore reasonable to assume that it experiences a statistically steady flow despite its motion.

Alongside the stereo-PIV and 5-hole probe measurements, the lift, drag and side forces, as well as the rolling, pitching and yawing moments were measured using an in-house force balance. The balance's dynamic range for the drag component was ± 1730 N, with an uncertainty lower than 1.7 N.

3.3 General characterization of the wake

Figures 3 and 4 present the overall structure of the flow for $\alpha = 9^\circ$ and 18° respectively. The mean flow is given in Fig. 3, in which the contour plot gives the mean streamwise velocity component, while the vectors illustrate the velocity field in the plane normal to the stream. Since the wake is slightly asymmetrical, all graphs have been evaluated on the left half of the model, for the sake of a fair comparison. The right plots of figures 3 and 4 are in fact mirror images of the actual flow.

For $\alpha = 9^\circ$, the wake features a small vortex core, which forms at the very tip of the model around $|y| = 0.45$ m. This primary vortex is accompanied by a narrow vortex sheet, which develops as the flow smoothly passes around the body of the model. At this setting, the level of turbulent fluctuations is negligible, and reaches only a couple of percents in the very core of the tip vortex. By contrast, the wake for $\alpha = 18^\circ$, is dominated by a large vortex in the form of a kidney bean. This particular shape is typical of several unsteady vortices interacting with each other. As a matter of fact, Schütte *et al.* [19] showed that for $\alpha = 18^\circ$, the tip vortex merges with a secondary vortex originating from the apex of the model. The unsteadiness of this process is confirmed by the maps of turbulent fluctuations displayed in Fig. 4, which shows a high level of normal turbulent stresses in the tip vortex region, reaching up to 10% of the free-stream kinetic energy.

In all cases, a strong cross flow is induced in the vicinity of the tip vortices, whose intensity reaches, in average up to 10% for $\alpha = 9^\circ$ and 20% for $\alpha = 18^\circ$.

4 Experimental methods

4.1 Accuracy of the reconstructed pressure fields

The crux of the matter relies here in reconstructing the static and stagnation pressure fields in the downstream plane, from PIV measurements. In order to assess how reliable these reconstructed fields are, Figs. 5 and 6 compare streamwise profiles of PIV-reconstructed static and stagnation pressure to profiles stemming directly from 5-hole probe wake measurements. In both

Fig. 5 Spanwise profiles of static pressure integrated vertically. Solid lines refer to direct pressure measurements with a 5-Hole probe. Dashed lines refer to the reconstructed static pressure based on PIV measurements fed into Eq. 13.

figures, the profiles are plotted along the left side of the model, as 5-hole probe measurements were available only there.

These two figures strikingly show that the reconstructed static and stagnation pressure fields compare quite differently to their 5-hole probe counterparts. Indeed, the reconstructed static pressure (Fig. 5) is systematically lower than the direct probe measurements, while the reconstructed stagnation pressure (Fig. 6) appears to be much closer to the probe measurements, except for $\alpha = 18^\circ$. Interestingly, the reconstructed stagnation pressure at low angles of attack appears to be quite accurate despite the fact that its computation uses a rather crude estimate of the static pressure field by virtue of Eq. 15. This observation therefore suggests that the underestimation of the reconstructed static pressure is in fact mitigated by the velocity field, making the reconstructed stagnation pressure a more robust quantity for the purpose of wake integral methods.

This is confirmed in Fig. 7, which compares two different methods of computing the stagnation pressure, based on Eq. 15. The first method consists in deducing P_i from the static pressure, as done previously, while the second method consists in computing P_i by imposing a uniform pressure throughout the wake plane. Interestingly, this figure shows that the global features of the stagnation pressure field can indeed be captured with the velocity field alone. However, in order to capture the stagnation pressure losses in the core of the tip vortex, it is preferable to compute P_i from a prior computed, albeit coarse, static pressure field.

The discrepancy between the static and stagnation pressure reconstructed from PIV data, and their di-

Fig. 7 Different options for the computation of the stagnation pressure. The solid line is associated to the direct five-hole probe measurements; The dashed line refers to P_i computed from Eq. 15 fed with the prior computed static pressure P ; The dash-dotted line shows the result of computing P_i with Eq. 15 in which an isobar wake plane at P_{∞} is imposed.

rectly measured counterparts is better quantified by defining C_P and C_{Pi} as

$$C_P = \int_{S_1} (P_{\infty} - P) dy dz, \quad (16)$$

and

$$C_{Pi} = \int_{S_1} (P_{i\infty} - P_i) dy dz, \quad (17)$$

and subsequently the relative differences ϵ_P and ϵ_{Pi}

$$\epsilon_P = \frac{|C_P^{5HP} - C_P^{PIV}|}{C_P^{5HP}}, \quad (18)$$

and

$$\epsilon_{Pi} = \frac{|C_{Pi}^{5HP} - C_{Pi}^{PIV}|}{C_{Pi}^{5HP}}, \quad (19)$$

where superscripts “5HP” and “PIV” refer to integrals evaluated with 5-hole probe and PIV measurements respectively. Table 1 reports these ratios for all angles of attack investigated.

Table 1 Relative differences between C_P and C_{Pi} computed with 5-hole probe data and PIV measurements.

α	ϵ_P	ϵ_{Pi}
9°	0.85	0.04
13°	0.45	0.07

4.2 Wake identification

As accurate as the stagnation pressure estimate may be (whether directly measured or reconstructed), it still yields poor global results once integrated throughout the downstream plane, as stagnation pressure losses do not exactly vanish outside of the wake due to noise and uncertainties. It thus becomes necessary to extract the wake from its surrounding to enforce that stagnation pressure losses are confined there.

The wake is identified by investigating the stagnation pressure distribution function, which presents a sharp discontinuity. A threshold value on the maximum admissible stagnation pressure loss is then imposed based on the value at which this discontinuity occurs (cf. the dotted line in Fig. 8). Fig. 9 shows the outer envelop of all the points lying beneath the aforementioned threshold, and confirms that the discontinuity in the stagnation pressure’s distribution function indeed coincides with the physical boundaries of the wake. From here on, the integration of the stagnation pressure is limited to this boundary. The procedure above is illustrated here for $\alpha = 13^\circ$, but works equally well at other angles of attack.

Fig. 8 Distribution function of $P_i/P_{i\infty}$ for $\alpha = 13^\circ$. The dotted line locates the discontinuity in the histogram, whose argument is taken as the threshold value between the actual wake and its surrounding.

4.3 Sensitivity to spatial resolution

Tables 2 and 3 show the sensitivity of the mechanical and phenomenological methods to the spatial resolution of the PIV data, which is given by the size of the interrogation windows (WS). Unsurprisingly, the two drag contributions that appear to be the most sensitive to the spatial resolution are those involving the reconstructed pressure field, namely C_D^{Press} and C_D^{Prof} , with a variation of forty to fifty drag counts between the highest and lowest resolutions (one drag count represents a 10^{-4} variation of the drag coefficient). Furthermore, decreasing the spatial resolution affects the convective and turbulent contributions by about 10 drag counts in each case, as a result of C_D^{Conv} 's and C_D^{Turb} 's integrands missing the finer flow structures. Interestingly, the induced drag term is the least sensitive, and shows a variation of only 6 drag counts between the finest and coarsest cases, despite this term representing the velocity gradients in the plane perpendicular to the stream.

Table 2 Sensitivity of the *mechanical* decomposition to spatial resolution, for the $\alpha = 13^\circ$ case. Computations are performed using PIV interrogation windows of increasing sizes (WS).

WS [pixels ²]	C_D^{Conv}	C_D^{Press}	C_D^{Turb}	C_D^{Mec}
32×32	0.0294	0.0164	-0.0016	0.0442
64×64	0.0293	0.0157	-0.0012	0.0438
128×128	0.0283	0.0128	-0.0007	0.0404

Table 3 Sensitivity of the *phenomenological* decomposition to spatial resolution, for the $\alpha = 13^\circ$ case. Computations are performed using PIV interrogation windows of increasing sizes (WS).

WS [pixels ²]	C_D^{Prof}	C_D^{Ind}	C_D^{Turb}	C_D^{Phen}
32×32	0.0205	0.0390	-0.0016	0.0579
64×64	0.0196	0.0391	-0.0012	0.0575
128×128	0.0151	0.0384	-0.0007	0.0528

4.4 Sensitivity to longitudinal discretization

Earlier work focused on reconstructing a pressure field from planar PIV highlighted the necessity to evaluate the derivatives in the out of plane direction (cf. for instance [23]) in order to get the most accurate predictions. The purpose of the following test is to assess the impact of the stream-wise gradients on the global drag predictions. To do so, we consider the three following schemes for the approximation of $\partial_x \mathbf{u}$ in Eq. 13, where for any function $\mathbf{u}(x, y, z)$:

$$\begin{cases} \frac{\partial \mathbf{u}}{\partial x} = 0 + O(1) \\ \frac{\partial \mathbf{u}}{\partial x} = \frac{\mathbf{u}(c_{\text{ref}} + \Delta x) - \mathbf{u}(c_{\text{ref}})}{\Delta x} + O(\Delta x) \\ \frac{\partial \mathbf{u}}{\partial x} = \frac{\mathbf{u}(c_{\text{ref}} + \Delta x) - \mathbf{u}(c_{\text{ref}} - \Delta x)}{2\Delta x} + O(\Delta x^2) \end{cases} \quad (20)$$

The first scheme is a shorthand for neglecting longitudinal velocity gradients altogether. In the following, an interrogation window of size 32×32 pixels² is used. Practically speaking, $\Delta x = 30$ mm is taken to be the spacing between adjacent PIV planes, while $x = c_{\text{ref}}$ refers to PIV measurements obtained in the middle plane located one chord away from the model's wingtips (cf. Fig. 2).

Table 4 shows that in the case at hand, neglecting longitudinal velocity gradients in the pressure reconstruction algorithm has a somewhat larger effect on C_D^{Press} , than C_D^{Prof} , with a variation of up to twelve drag counts for the former vs. four for the latter. This again seems to indicate that the stagnation pressure is a more robust quantity than the plain static pressure. In any case, the sensitivity of either C_D^{Press} or C_D^{Prof} to the discretization scheme appears to be marginal, when compared against their respective sensitivity to the spatial resolution of the data, which suggests that it is the latter that should be given priority when computing loads from wake data.

Fig. 9 Wake contour for $\alpha = 13^\circ$, as identified by the threshold value found in Fig. 8. This figure showcases the importance of cropping the wake's surrounding before integration, as the latter introduces artificial stagnation pressure losses, which have no physical meaning.

Table 4 Sensitivity of C_D^{Press} and C_D^{Prof} to the order of the discretization scheme used in Eq. (13), for the $\alpha = 13^\circ$ case. Results are obtained with PIV interrogation windows of size 32×32 pixels².

Scheme order	C_D^{Press}	C_D^{Prof}
0	0.0152	0.0201
1	0.0158	0.0207
2	0.0164	0.0205

5 Results and discussion

To begin with, table 5 gives the global drag coefficients measured by the force balance, which will be used as a reference throughout the remainder of the text. The relatively high measurement dispersion of 8% for $\alpha = 9^\circ$ comes from the low drag value occurring at this angle of attack, with respect to the balance's dynamic range.

Table 5 Reference drag coefficients measured using a force balance, for the angles of attack $\alpha = 9^\circ$, 13° and 18° .

C_D^{Bal}		
$\alpha = 9^\circ$	$\alpha = 13^\circ$	$\alpha = 18^\circ$
0.0233 ± 0.0018	0.0543 ± 0.0016	0.171 ± 0.0034
($\pm 8\%$)	($\pm 3\%$)	($\pm 2\%$)

Tables 6 and 7 display the global drag predictions and their breakdown, stemming from the mechanical (Eq. 3) and phenomenological (Eq. 9) approaches, as well as the relative difference between the global predictions and the balance measurements. Before computing the drag coefficients, the wake of the model holder was masked to remove its contribution to the total drag. Failing to do so would have resulted in an artificially

inflated drag coefficient, since the model was directly mounted onto the force balance, at the tip of the holder.

According to tables 6 and 7, the mechanical and phenomenological methods yield global drag predictions that lie within 10% of the balance measurements, except for the mechanical prediction at $\alpha = 13$, which is off by almost 20%. Furthermore, the mechanical breakdown appears to systematically underestimate the balance measured drag coefficients. In light of Fig. 5, this behavior likely results from the inaccurate reconstructed pressure from PIV measurements, which tends to miss the amplitude of the depression inside the tip vortex core. By comparison, the drag coefficients computed using the phenomenological decomposition systematically overestimate those measured with the force balance.

Table 6 Total mean drag predictions and their breakdown, as given by the *mechanical* approach. Computations are performed using the finest PIV resolution of 3 mm (32×32 pixels² interrogation windows). Values in parentheses are relative differences with respect to the balance measurements.

α	C_D^{Conv}	C_D^{Press}	C_D^{Turb}	C_D^{Mec}
9°	0.0169	0.0048	-0.0007	0.0210 (-10%)
13°	0.0294	0.0164	-0.0016	0.0442 (-19%)
18°	0.1067	0.0684	-0.0131	0.1620 (-5%)

Table 7 sheds some light on the relative competition between the physical processes at play. In particular, the phenomenological breakdown displays a reversal in the competition between the induced and the profile drag, with the former dominating at low angles of attacks ($\alpha = 9$ and 13°), and the latter at $\alpha = 18^\circ$. By contrast such a reversal does not transpire in the mechanical breakdown, for which the convective term always dominates. This observation may be physically interpreted in the light of Schütte *et al.*'s study [19], which shows that $\alpha = 18^\circ$ coincides with the tip vortex

Fig. 10 Spanwise profiles of drag contributions for $\alpha = 9^\circ$. (Left) mechanical decomposition: each black line represents a particular term of Eq. (3) integrated along z ; (Right) phenomenological decomposition: each black line represents a particular term of Eq. (9) integrated along z . For both cases, the red line represents the cumulative integral of all terms: the reading at $y = 0$ gives the total drag produced on one half of the wing.

being at the onset of bursting. From this point onward, the tip vortex progressively detaches from the upper surface of the model, therefore decreasing lift, hence also decreasing induced drag. Simultaneously, the resulting flow separation promotes pressure drag, which leads to an increase in profile drag. Such observations can prove quite valuable when optimizing an airframe for a particular flight regime, since tackling induced or profile drag requires radically different strategies. For

instance, optimizing profile drag hints at reducing skin friction or delaying the flow separation, while reducing induced drag is usually tackled by preventing the formation of trailing vortices with wingtip devices. Inferring such strategies based on the mechanical decomposition alone would not be possible, since the competition between its different contributions may not automatically translate into physically interpretable drag sources.

The previous argument is illustrated with a more local point of view in Figs. 10 and 11, which present spanwise profiles of mechanical and phenomenological drag, obtained by respectively integrating Eqs. 3 and 9 along the z coordinate. Here, the cases $\alpha = 9$ and 18° are considered. As before, all graphs are evaluated along the left half of the wing, the right parts of figures 10 and 11 being mirror images. For $\alpha = 9^\circ$, the phenomenological decomposition (Fig. 10, right) concentrates drag in a narrow region of the wake which coincides with the location of the tip vortex's core. By contrast, the mechanical method (Fig. 10, left) associates drag for some

part at the location of the tip vortex, but mostly along the model's centerline, where a deficit in the longitudinal velocity component appears, as mean kinetic energy has been redistributed into the cross flow. For $\alpha = 18^\circ$ however, the region of the wake mainly associated to the momentum deficit is clearly associated to the tip vortex. One must remain cautious when interpreting the wake in terms of drag production, since the latter only gives a picture of what the flow encountered along the model's surface, where drag was actually produced via pressure and skin friction. It can nonetheless yield some insight, especially in the presence of dominating flow structures such as here.

Finally, Figs. 10 and 11 show the cumulative integral of all the different contributions to the mechanical and phenomenological breakdown, where the value read on the model's centerline corresponds to the total drag produced by one half of the model. It should be observed that though the mechanical and the phenomenological methods translate in radically different spanwise profiles, they eventually integrate to similar values (within their respective accuracy), thus confirming that the two methods described in this paper are in fact two different points of view of the same phenomenon.

To put the current work in perspective with the existing literature, the global drag predictions obtained here (whether using the mechanical or phenomenological method) appear to be at par with those published in earlier studies dealing with the same issue. Indeed, as far as wake surveys using the phenomenological decomposition fed with 5-hole probe measurements is concerned, Brune [2] reports a relative difference better than 1% with respect to balance measurements on the drag prediction of a 1.80 m long rectangular wing, while Crowder *et al.* [3] reports a 13% difference between balance measurements and the wake drag prediction of civil aircraft model flying at $Ma = 0.86$. In this case, the main source of error is attributed to the method not accounting for flow compressibility effects.

Regarding load evaluation using the mechanical approach fed with PIV data, Ragni *et al.* reports drag values that lie within 10% of those obtained using a pitot wake rake behind a NACA0015 airfoil, while the drag prediction acting on a 2D square cylinder of Kurtulus *et al.* underestimates the expected value by 20% to 30%. In addition, De Kat & Bleischwitz [6] measured drag coefficients from a wake survey behind a flat plate, and reported drag coefficients within 30% of direct force measurements. The latter authors computed the total mean drag based on Eq. (2) fed with a flow field reconstructed from PIV measurements of a sub-region of

the wake. The flow in the entire downstream plane $\mathcal{S}_1$ was then inferred by invoking its symmetry with respect to the centerline, and its solenoidality. They thus attributed the relatively large discrepancies to the fact that they did not have access to the entire flow field. In that respect, the phenomenological method would perhaps be more suited, as it naturally vanishes outside of the wake. Based on the present work however, another aspect that may have had an impact in their results might be their assumption of an exactly symmetrical wake. Though reasonable in a first approximation, Fig. 9, and the cumulative values of Figs 10 and 11 which are systematically lower than half the total drag coefficient gives evidence that this may not always be exactly true.

6 Conclusion

This paper benchmarks the phenomenological drag breakdown method against the traditional control volume approach based on a global balance of momentum, using stereo-PIV data acquired in the complex wake of a finite-size wing. The former method expresses drag in terms of profile and induced drag, while the latter expresses drag in terms of the surrounding flow's properties. Until now, the phenomenological decomposition was numerically evaluated with five-hole probe measurements.

In the particular case at hand, we have shown that the mechanical and phenomenological methods perform similarly, as they yield integrated drag coefficients almost always within 10% of the balance measurements. Furthermore, we have illustrated how the phenomenological method can be used to physically interpret the drag sources at play, which can ultimately be used to optimize an airframe's geometry for a particular flight regime. By contrast, the mechanical approach does not allow one to distinguish between the different physical origins of drag, as it entangles the convective and pressure effects together.

As far as the implementation of the methods is concerned, this study highlights by comparing the PIV-reconstructed static and stagnation pressure to direct five-hole probe measurements, that the latter is a more robust quantity than the former. This behavior likely results from the fact that the stagnation pressure in fact mitigates information about the reconstructed static pressure with information about the PIV-measured velocity field. In that respect, the phenomenological method appears to be particularly well suited to the investigation of aircraft wakes containing intense trailing edge vortices, as it enables one to reduce the integration domain based on physical arguments alone.
