ABSTRACT

Antibiotic resistance is a global public health issue and metal exposure can co-select for antibiotic resistance. We examined genome sequences of three multi-drug and metal resistant bacteria: one *Shewanella* sp., and two *Vibrio* spp., isolated from the gut of the mummichog fish (*Fundulus heteroclitus*). Our primary goal was to understand the mechanisms of co-selection. Phenotypically, the strains showed elevated resistance to arsenate, mercury, and various types of β -lactams. The genomes contained genes of public health concern including one carbapenemase (*bla_{OXA-48}*). Our analyses indicate that the co-selection phenotype is mediated by chromosomal resistance genes and cross-resistance. No evidence of co-resistance was found; most resistance genes were chromosomally located. Moreover, the identification of many efflux pump gene homologs indicates that cross-resistance and/or co-regulation may further contribute to resistance. We suggest that the mummichog gut microbiota may be a source of clinically relevant antibiotic resistance genes.

1. Introduction

Antimicrobial resistance is a pressing public health concern that threatens the usage of effective antibiotic therapies and the global healthcare system. Multi-drug resistance (MDR) in Gram-negative bacteria is currently increasing at an alarming rate (Ventola, 2015). Antibiotic resistance genes (ARGs) are found in many environments (Pal et al., 2016) including ancient (30,000 year-old) permafrost sediments (D'Costa et al., 2006). Environmental reservoirs of resistance genes remain poorly understood (Allen et al., 2010). In order to combat the growing threat of MDR, it is important to understand the processes and pathways by which MDR is created and spread in the environment.

The aquatic environment is increasingly being recognized as an important reservoir for ARGs (Kang et al., 2016). Exposure to a plethora of persistent contaminants, including metals, promotes the selection of resistant indigenous microbiota. Coastal marine environments, at the boundary between terrestrial, freshwater, and marine environments, are of particular importance in this paradigm as they are locations with large and rapidly growing population centers (Culliton, 1998). The release of contaminants to productive coastal ecosystems where ARGs may spread and be selected for, may lead to the exposure of large human population centers to antibiotic-resistant bacterial pathogens (Zhu et al., 2017). For this reason, estuaries, typical ecosystems at the land-sea boundary, have been a focus of much research on the effect of environmental contamination on the spread of antibiotic resistant

bacteria and ARGs for quite some time (Lu et al., 2015).

Exposure to contaminants, especially metals, may promote the spread of antibiotic resistance in the environment through a process known as co-selection (Baker-Austin et al., 2006). Co-selection is mediated through several mechanisms including co-resistance, cross-resistance, and co-regulation. Co-resistance occurs when genes encoding for antibiotic and metal resistances are located proximally to each other in a genome, particularly on mobile genetic elements. Horizontal gene transfer of ARGs has been widely studied, and conjugation is generally considered the most common mechanism (Pal et al., 2017). Generally, co-resistance plasmids are commonly found in bacteria isolated from humans or domestic animals (Pal et al., 2015). Another mechanism by which co-selection occurs is via cross-resistance, when the same system (e.g. efflux pumps) confers resistance to both antibiotics and metals (Baker-Austin et al., 2006). Multidrug efflux pumps are wide-spread and well-conserved elements thought to have evolved for life in enteric environments (Blanco et al., 2016). They are known to extrude a wide range of substrates from the cell, not only antibiotics and metals, but also plant-produced compounds, quorum sensing signals, and bacterial metabolites (Blanco et al., 2016). While there is still a lack of knowledge on some of the specificities of these pumps, particularly about how they are regulated, efflux systems have been identified as contributing to MDR in *Enterobacteriaceae* (Webber et al., 2003). The third way by which co-selection occurs is through the transcriptional co-regulation of resistance genes. For example, heavy

metal ions can increase regulation of efflux systems (e.g. the AcrAB efflux pump in *E. coli*), which results in increased resistance towards antibiotics (Seiler et al., 2012). While numerous studies have documented the occurrence of MDR among environmental microbes (e.g., (Kang et al., 2016; Lima-Bittencourt et al., 2007) and reviewed in: (Wright et al., 2006)), few have examined the molecular mechanisms responsible for this phenomenon.

We previously reported on the isolation of multi-drug and mercury resistant bacteria from the mummichog (*Fundulus heteroclitus*) gastrointestinal tract and showed that mercury resistant strains were more likely than sensitive strains to be resistant to multiple antibiotics (Lloyd et al., 2016). These results led us to consider the mechanisms that facilitate co-selection of metal and antibiotic resistances in our isolates. Here we used the power of whole genome sequencing to identify antibiotic resistance genes and their association with metal resistance genes in two *Vibrio* spp. and one *Shewanella* sp., which are known to make up a large portion of the wild mummichog gut intestinal microbial community (Givens et al., 2015). These strains belong to genera that include opportunistic pathogens and are considered vehicles of MDR (Janda, 2014; Yousfi et al., 2017a). *Shewanella* spp., primarily, *S. algae* and *S. putrefaciens*, have been implicated in human infections (Cimmino et al., 2016) and are known to harbor ARGs of public concern (Yousfi et al., 2017b). *Vibrio* are abundant in coastal waters, and their ability to develop and acquire ARGs in response to selective pressure and to further spread ARGs by horizontal gene transfer has been documented (Dang et al., 2009). *Vibrio parahaemolyticus* is a causative agent of food poisoning. *V. anguillarum* is a recently discovered species of *Vibrio* and it has not been shown to be pathogenic to humans, however, its genome does contain genes involved in pathogenicity.

Our results indicate that while the aquatic bacteria studied did indeed harbor many ARGs of clinical importance, evidence for co-resistance in the genomes was unfounded. Rather, we found evidence to support chromosomally-encoded resistance genes as well as potentially cross-resistance and/or co-regulation as mechanisms of co-selection of MDR and metal resistance.

2. Methods

2.1. Isolation

Strains were isolated from mummichog (*Fundulus heteroclitus*) gut ingesta collected from Berry's Creek in Bergen County, New Jersey, and Great Bay, part of Rutgers University Marine Field Station in Tuckerton, New Jersey during the summer of 2014. For details on isolation methods, refer to Lloyd et al. (2016). To taxonomically identify the strains at the genus level, colony PCR of the partial 16S rRNA gene was performed using the 27F/519R universal primers (Lane, 1991) and the sequences were compared to NCBI (Madden, 2002).

2.2. Antibiotic susceptibility testing

Antibiotic susceptibility to the following 14 compounds (0.125–64 µg/mL) was carried out by the broth microdilution method according to the guidelines of the Clinical Laboratory Standards Institute (CLSI) using microtiter plates: cefazolin, cefoperazone, ceftazidime, ceftazidime, kanamycin, meropenem, nalidixic acid, penicillin, sulfamethoxazole, streptomycin, tetracycline, ticarcillin, ticarcillin-clavulanic acid, and vancomycin. Additionally, all strains were tested by the disk diffusion method for their susceptibility to amikacin (30 µg), aztreonam (30 µg), cefepime (30 µg), cefoxitin (30 µg), cefpirome (30 µg), ceftazidime (30 µg), chloramphenicol (30 µg), ciprofloxacin (5 µg), doripenem (10 µg), gentamicin (15 µg), imipenem (10 µg), levofloxacin (5 µg), meropenem (10 µg), minocycline (30 µg), netilmicin (30 µg), ofloxacin (5 µg), pefloxacin (5 µg), piperacillin (75 µg), piperacillin-tazobactam (75/10 µg), rifampicin (30 µg), tetracycline (30 µg), ticarcillin (75 µg), ticarcillin-clavulanic acid (75/10 µg), tobramycin

(10 µg), trimethoprim-sulfamethoxazole (1.25/23.75 µg). Testing was performed according to the guidelines of the CLSI using commercially available disks (Bio-Rad, Marne-la-Coquette, France). Since resistance profiles are not well established for environmental bacteria, prior reports including the *Enterobacteriaceae* table (Soussy et al., 2013), clinical break points (Clinical Laboratory Standards Institute, 2012), and *Vibrio* breakpoints (Bier et al., 2015) were used in combination to determine resistance.

2.3. Metal susceptibility testing

Metal resistance testing was carried out using the Bioscreen C (Oy Growth Labs Ab Ltd), an automated microbiology growth curve analysis system. Pre-cultures were grown on solid tryptic soy agar media overnight at 28 °C. Colonies were suspended in tryptic soy broth liquid media to a McFarland standard of ~1.5 measured using the Densicheck system (bioMérieux, Craponne, France). Approximately 4.5×10^6 CFU/mL were inoculated into Bioscreen C honeycomb plates containing various concentrations of the following (freshly prepared) metals: nickel chloride hexahydrate (1–16 mM), cadmium chloride hemihydrate (0.31–10 mM), mercury (II) chloride (12.5–200 µM), potassium arsenate (3.12–200 mM), and sodium arsenite (3.12–50 mM), with uninoculated media as a negative control, and cultures grown in the absence of metals as a positive control. Assays were run in triplicate wells. Bioscreen plates were incubated at 28 °C, with agitation, and OD at 600 nm measurements were taken every 20 min.

2.4. Growth rate calculations

Growth rates (μ) of the triplicate wells from the Bioscreen C assays were determined using the grofit package for R (Kahm et al., 2010). Briefly, media blanks were subtracted from absorbance readings from raw Bioscreen data. These corrected values were analyzed in grofit. The averages and standard deviations of the growth rates were visualized in Microsoft Excel.

2.5. DNA extraction

Strains were grown overnight in LB liquid media amended with 100 µg/mL ampicillin. Genomic DNA was extracted using the QIAamp DNA Mini Kit (Qiagen). Plasmid DNA was extracted using the Macherey-Nagel Plasmid DNA purification kit (Macherey-Nagel, Hoerd, France). Genomic and plasmid DNA samples were combined and sent to Molecular Research DNA Labs in Shallowater, TX, USA, for sequencing according to company protocols.

2.6. Annotation and analysis

Reads were assembled into contigs using SPAdes Genome Assembler (Bankevich et al., 2012). Genomes were annotated using the NCBI Prokaryotic Pipeline (Tatusova et al., 2016) and genome sequences are available under the assembly numbers reported in Table 1. Average Nucleotide Identity (ANI) (Yoon et al., 2017) was calculated using the whole genome sequences. Genomes were examined using Geneious version 10 (www.geneious.com; (Kearse et al., 2012)). Potential plasmids were identified as contigs with high copy numbers (since they were extracted separately) in sequencing data. We then searched for plasmid maintenance gene homologs and as well as comparison to known plasmids. Genomic Islands were identified using IslandViewer 4 (Bertelli et al., 2017). Putative AMR genes were detected by a blast (Madden, 2002) search using ARG-ANNOT V3 March 2017, accessed November 2017 (Gupta et al., 2013). Putative metal resistance genes were detected by a blast search using the experimentally-confirmed BacMet metal resistance genes database version 1.1 (Pal et al., 2013) accessed December 2017. Gene homologs from both databases with E values < $10e^{-20}$ are reported. Efflux pump genes were identified using

the BacMet database as well as manual scanning of the genome annotations. Metal resistance and antibiotic resistance genes were referenced with results of IslandViewer 4, to visualize if any resistance gene determinants were also on putative genomic islands. To determine the sub-groups of the p-type ATPase proteins, 80 representative p-type ATPases (Smith et al., 2014) were downloaded from UniProtKB (Bairoch et al., 2007), and a phylogenetic tree (not shown) was built from the alignment of the proteins.

3. Results

3.1. Taxonomic identification and genomic properties

Among the 52 bacteria we isolated from the mummichog gut microbiome, the two most dominant taxa were *Vibrio* (62%) and *Shewanella* (21%) (Fig. S1). *Shewanella* sp. BC20 was isolated from the gut ingesta of fish collected from Berry's Creek, an EPA superfund site contaminated with mercury and arsenic, located in New Jersey, USA (Wright et al., 2010). *Vibrio* spp. T9 and T21 were isolated from the gut ingesta of mummichog fish collected from Great Bay, New Jersey, USA, a relatively uncontaminated site (Lloyd et al., 2016). The average nucleotide identities (ANI) with scores above 95% were used to identify the available genome to which our strains were most closely related. Of those available in NCBI as of May 2016, *Shewanella* BC20 was most closely related to *Shewanella* sp. MR-4, a strain isolated from the water

*Levels of resistance are reported in MIC µg/mL (for those tested with the microdilution method) or zone of inhibition in mm (for those tested with the disk method).

**Organisms are reported as S (sensitive), I (intermediate), or R (resistant) as established by common standards. For a complete list of all antibiotics tested, and sources for common standards used in determining break points, see Table S1.

***Shading indicates that a resistance gene homolog potentially conferring resistance to that antibiotic was found in the genome regardless if the strain was phenotypically resistant or sensitive to that drug.

****Comparable resistance breakpoints for this drug could not be found.

Table 3
Antibiotic resistance gene homologs with clinical relevance and their respective locus tags in the three genomes.*

Antibiotic class	Putative gene	Substrates/function	<i>Vibrio</i> sp. T9	<i>Vibrio</i> sp. T21	<i>Shewanella</i> sp. BC20
			Locus	Locus	Locus
β -lactams	Class A β -lactamase (CARB)	Penicillins, cephalosporins, carbenicillin (Chiou et al., 2015)	CBX98_10150	CCD93_08640	
	Class B metallo β -lactamase	Broad spectrum, including carbapenems, (Palzkill, 2013)	CBX98_12520	CCD93_19270	CBX96_13965

* The table shows select antibiotic resistance gene homologs located in the genome.

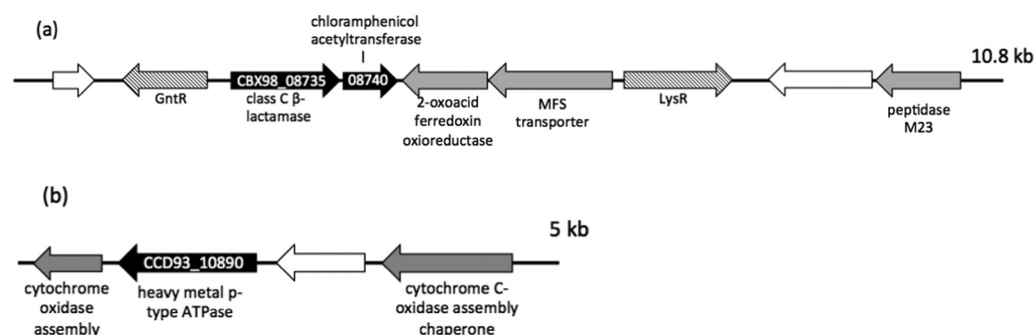

Fig. 1. Genomic Islands containing genes of interest located in *Vibrio* sp. T9 (A) and *Vibrio* sp. T21 (B). The genomic island in (A) contains two antibiotic resistance genes and the island in (B) contains one metal resistance gene (colored black). Hypothetical proteins are colored white, genes involved in transcriptional regulation are shaded with diagonal lines, and all other genes are in grey. Arrows indicate direction of transcription.

column of the Black Sea at a depth of 5 m (Nealson et al., 1991). *Vibrio* sp. T9 was most closely related to *Vibrio antiquarius* EX25, a *Vibrio* isolated from hydrothermal vents (Hasan et al., 2015), and *Vibrio* sp. T21 was most closely related to *Vibrio parahaemolyticus* FORC 018, a strain isolated from sea bass in South Korea (Table 1). *Shewanella* sp. BC20 had an average G + C% of 48.0%, which is identical to that reported for *Shewanella* sp. MR-4. (GenBank Accession CP000446.1). The genome of *Shewanella* sp. BC20 contained no plasmids (Table 1). The average G + C% of the two *Vibrio* strains, *Vibrio* spp. T9 and T21, were 45.0 and 45.4%, respectively, which is within the normal range for *Vibrio* species (Hasan et al., 2015). Strain *Vibrio* sp. T9 contained one 120 kb plasmid, with a G + C% of 44.7%, close to that of the chromosome. The plasmid showed 94% nucleotide identity (with 65% query cover) to *V. alginolyticus* ATCC 33787 plasmid pMBL128 (Accession number CP013486.1).

3.2. Antibiotic susceptibility profiles

Resistance to 33 antibiotics was tested using established procedures, a combination of the disk method and the microdilution method (Tables 2, S1). Of those drugs tested with both the disk method and the microdilution method, we obtained consistent results among carbapenems, penicillins, tetracyclines, and most cephalosporins. All three strains showed broad resistance to β -lactams, primarily cephalosporins and penicillins. The two *Vibrio* strains were intermediately resistant to aminoglycosides. The resistance profile of *Shewanella* sp. BC20 was varied, including resistance to carbapenems as well as to vancomycin. All strains were sensitive to tetracycline and chloramphenicol.

3.3. Antibiotic resistance genes

Overall, our analysis identified 70 potential ARG homologs in *Shewanella* sp. BC20, 78 were identified in *Vibrio* sp. T21, and 89 in *Vibrio* sp. T9 (Tables S2, S3, S4). ARG homologs of clinical relevance are reported (Table 3). All four Ambler classes of β -lactamases were identified among the three strains. All three harbored class B metallo- β -lactamases. *Vibrio* sp. T9 contained a class C β -lactamase located on a

Fig. 2. A-C. Effect of increasing concentrations of arsenate and mercury on growth rates of the three mummichogs bacterial isolates. Each point represents average growth rates of 3 replicates \pm standard deviation.

genomic island (Fig. 1). Strains *Vibrio* spp. T9 and T21 both contained class A carbenicillin hydrolyzing β -lactamases (CARB). The amino acid % identity of the two CARB genes was 88.3%, indicating they are closely related to each other but not identical (Table 3). *Shewanella* sp. BC20 harbored a class C β -lactamase as well as an extended spectrum β -lactamase (ESBL), *bla*_{OXA-48}. The two *Vibrio* spp. harbored tetracycline (*tet34* and *tet35*) and chloramphenicol resistance genes yet were susceptible to those drugs (Tables 2,3). *Vibrio* spp. T9 and T21 harbored *qnrS*, which confers resistance to quinolones (Table 3). The *Vibrio* spp. were phenotypically sensitive to nalidixic acid and most of the fluoroquinolones tested, however *Vibrio* sp. T21 was intermediately resistant to ofloxacin (Table 2, S1). Further, the genomes harbored many efflux pump gene homologs from various families including ABC, MATE, MFS, RND, and in the *Vibrio* spp., SMR (Tables S5, S6, S7). The type and abundance found in each were comparable to reference strains (Fig. S2). Notably, *Shewanella* sp. BC20 contained 13 operons for RND efflux pumps, *Vibrio* sp. T9 contained 12, and *Vibrio* sp. T21 contained 13.

3.4. Metal resistance profiles

Compared to other metal resistance studies in *Vibrio*, *Vibrio* spp. T9 and T21 were resistant to cadmium (5 mM) (data not shown) (He et al., 2016) and arsenate (100 mM) (Liao et al., 2011). *Vibrio* sp. T21 was also resistant to mercury (50 μ M) (Fig. 2A–B) (He et al., 2016). *Shewanella* sp. BC20 was able to grow with 50 mM arsenate and 25 μ M mercury (Fig. 2C). All three strains were sensitive to the tested concentrations of arsenite and nickel.

3.5. Metal resistance genes

The genomes of the three strains contained operons for arsenate resistance and metabolism (i.e., arsenite oxidation/arsenate reduction) (Table S8, S9). They also contained genes for various P-type ATPases (Table S10). *Vibrio* spp. T9 and T21 each contained two *P*_{1B-1}-ATPases and one *P*_{1B-2}-ATPase. *Shewanella* sp. BC20 contained two *P*_{1B-1}-ATPases. Not including efflux pump genes, in total, *Shewanella* sp. BC20 contained 148 homologs for genes involved in metal resistance, while *Vibrio* sp. T9 had 149, and *Vibrio* sp. T21 had 154 (Tables S11, S12, S13). The most abundant metal resistance genes among all three genomes were gene homologs for zinc, iron, copper, and nickel resistance.

3.6. Genomic islands and the mobilome

We searched for genomic islands in the strains, and more specifically, the carriage of ARGs and metal resistance genes on such islands as possible evidence for co-resistance. The genome of *Shewanella* sp. BC20 contained 16 genomic islands with one metal resistance gene (Table S14). *Vibrio* spp. T9 and T21 contained 29 and 23 genomic islands, respectively (Table S15, S16). *Vibrio* sp. T9's genome had one 10 kb genomic island that harbored genes encoding for a chloramphenicol acetyltransferase, a class C β -lactamase, and an MFS transporter (Fig. 1), all genes involved in drug resistance. *Vibrio* sp. T21's genome contained two genomic islands of interest: a large element (~25 kb) containing an MFS transporter gene, multidrug ABC transporter gene, and genes involved in horizontal gene transfer (IS3 family transposase) and a smaller genomic island (~5 kb), which contained a heavy metal translocating P-type ATPase (Fig. 1). Some of the metal resistance genes were located on genomic islands in the *Vibrio* spp. genomes: three in *Vibrio* sp. T9 and four in *Vibrio* sp. T21 (Tables S11, S12). All other ARGs and metal resistance genes are located elsewhere in their respective genomes with no proximity to other ARGs or to genes suggestive of horizontal transfer. We were unable to identify any genes of interest in proximity to phage genes.

4. Discussion

The aim of our study was to examine the genetic underpinning of co-selection in multi-drug and metal resistant bacteria isolated from the intestinal microbial community of the mummichog, a common coastal fish. The genome sequences revealed carriage of efflux pump gene homologs, metal resistance genes, and ARGs, including genes of public health concern. Overall, our results indicate that antibiotic and metal resistance are mediated by a variety of factors including chromosomally-encoded resistance genes and potentially efflux pumps. Our results show horizontally-acquired ARGs and metal resistance genes, which highlights the potential for horizontal acquisition of ARGs. Phenotypically, strains were resistant to various classes of antibiotics (primarily different types of β -lactams) as well as to metals.

The ease by which gene sequences are now obtained by metagenomic approaches has recently led to studies on the abundance and distribution of ARGs in environmental samples (e.g. (Marti et al., 2014; Guo et al., 2017)). While these studies have been useful in assessing hot spots where MDR is likely (e.g., (Berendonk et al., 2015)) they cannot identify the organisms and the mechanisms of gene transfer that partake in ARG transfer from environmental strains to clinical microbes (Perry et al., 2013). Additionally, even though metatranscriptome surveys may inform on the expression of ARGs in the environment (e.g., (Versluis et al., 2015)) how this expression is related to mobilome activities and microbial metabolism cannot be deciphered from such studies. As this information is crucial for the understanding of the ecological framework that underpins the spread of ARGs, metagenomic approaches must be complemented by pure culture studies that shed light on resistant taxa, their ARGs, and potential to mobilize these genes to clinical isolates.

Because MDR among Gram-negative bacteria is of public health concern (Hawkey, 2015), we chose to study three Gram-negative bacteria that represent dominant taxa, *Vibrio* spp. and *Shewanella* spp., in our collection (Lloyd et al., 2016) as well as in the mummichog gut microbiome (Givens et al., 2015). Our approach compared genotype (i.e., gene presence) with phenotype to gain an understanding of the carriage, expression, and location of antibiotic and metal resistance genes within the genomes.

Shewanella sp. BC20, isolated from a heavy-metal contaminated estuary, showed resistance to carbapenems, cephalosporins, and penicillins; three classes of drugs to which *Shewanella* are commonly susceptible (Janda, 2014). The strain showed an elevated resistance profile compared to the 28 out of the 33 environmental *Shewanella* isolates tested by Tacao et al. (Tacao et al., 2018), with resistance to 9 of the antibiotics reported. Further, the *Shewanella* sp. BC20 genome harbors a class D β -lactamase, *bla*_{OXA-48}, with the same upstream and downstream genetic context that others have reported (Tacao et al., 2018). Numerous reports suggest the occurrence of *bla*_{OXA-48} in environmental *Shewanella* spp. (Poirel et al., 2003) and its horizontal mobility and expression in human pathogens (Almuzara et al., 2017). One of the other isolates studied, *Vibrio* sp. T21, was intermediately resistant to ofloxacin (Table 2), a fluoroquinolone antibiotic. Resistance to ofloxacin has been attributed to a mutation in the *gyrB* gene (Singh et al., 2015) and possession of quinolone resistance genes has been described among fish-associated *Aeromonas* spp. (Chenia, 2016). Quinolones are synthetic antibiotics commonly recommended and used in treatment of vibriosis, including *V. parahaemolyticus* infections (Wong et al., 2015).

We identified members of all four Ambler classes of β -lactamases. Notably, all three strains harbored class B metallo- β -lactamases (MBLs), which confer resistance to almost all classes of β -lactam antibiotics. The so-called “New Delhi MBL”, is considered a threat to global public health as it is easily mobilizable and has been found in many countries world-wide (Rasheed et al., 2013). Studies have reported on previously unknown MBLs in soil microbiota, which present a clinical threat if acquired by pathogenic bacteria (Gudeta et al., 2016). Thus, the

occurrence of this gene among environmental organisms may contribute to community-acquired colonization as well as infections (Potron et al., 2011), and suggests the mummichog gut as a reservoir of clinically relevant antibiotic resistant organisms and their associated resistance genes. In order to understand this connection, we looked at the genetic linkage between metal and antibiotic resistance in the genomes. We expected evidence for co-selection suggesting horizontal gene transfer and selection due to heavy metal stress. This expectation was based on: 1) metal resistance genes are often found on mobile genetic elements (McIntosh et al., 2008), 2) the association of metal and antibiotic resistance genes on conjugative plasmids is well-documented (Clowes, 1972), and 3) the fish gut with its abundant nutrients and stable temperature is conducive to microbial growth and gene transfer (Sorensen et al., 2005).

Indeed, we identified two cases where ARGs and metal resistance genes were located on separate genomic islands, clusters of genes of probable horizontal origin (Bertelli et al., 2017). *Vibrio* sp. T9 contained a 10.8 kb genomic island with both a class C β -lactamase and a chloramphenicol acetyltransferase gene homolog (Fig. 1A) and *Vibrio* sp. T21 had a P_{1B-1} -ATPase, possibly specifying cadmium resistance, on a 5 kb genomic island (Fig. 1B). This suggests possible past acquisition of these genes. These putative genomic islands do not carry mobilome gene homologs (those involved in conjugation, phage, or transposition). Moreover, we were unable to identify other cases where genes of interest were proximally located to mobilome genes. The one large (~120 kb) plasmid in *Vibrio* sp. T21, contained no mobilome, antibiotic, or metal resistance genes. This plasmid did not have any gene homologs indicating potential for conjugation, indicating the plasmid may not be transferrable.

Genome sequences suggest that cross-resistance (efflux pumps) may contribute to co-selection. Each genome harbored many efflux pump gene homologs (66 in *Shewanella* sp. BC20, 128 in *Vibrio* sp. T9 and 117 in *Vibrio* sp. T21 (Tables S5, S6, S7). RND efflux pumps have been implicated in Gram-negative MDR, and both the *Shewanella* sp. BC20 and *Vibrio* sp. T21 contained an elevated number of RND-family efflux pump operons compared to previous reports (Lloyd et al., in preparation). This result is consistent with a recent report on the dominance of efflux pump-based cross-resistance in the whole genome sequence of an environmental *Pseudomonas* strain from a metal-contaminated estuary (Teixeira et al., 2016) and the increased extrusion of antibiotics via RND efflux pumps in marine biofilms exposed to heavy metals (Flach et al., 2017). These results highlight the need to examine cross-resistance as well as co-regulation as mechanisms of co-selection, ideas currently under investigation in our lab. The environmental selection of resistant strains may be the strongest driver of co-selection as was suggested by Forsberg et al., (2014) who assert that microbial community composition rather than horizontal gene transfer is the primary determinant of ARGs in soil.

One advantage of examining co-selection in three individual genomes over community analyses or PCR amplification assays is that it provides direct evidence for co-selection in individual organisms (Pal et al., 2017). We tested resistance of three strains to several different antibiotics using two standard methods; the genome sequences of these strains informed us on the presence and/or absence of corresponding resistance genes (Tables 2, S1). All three strains were resistant to ceftazidime using the MIC method, but sensitive in the disk method. Inconsistencies between results obtained with different types of antimicrobial testing methods were previously reported (Lehtopolku et al., 2011). There were several cases where the strains harbored resistance genes but were scored as sensitive to the drug (i.e., *tet* genes in *Vibrio* spp.) (Table 3). There were other cases where the strains did not harbor known resistance genes, but were scored as intermediately resistant to the drug (i.e., aminoglycosides in *Vibrio* spp.). Thus, if a study scores only gene presence, it may either over- or under-estimate the MDR phenotype of a strain. This conclusion is in agreement with recent recommendations for essential verifications if whole genome sequences of

pathogens are to serve in resistance profiling in the clinical lab (Lo et al., 2018).

All three strains contained an arsenal of putative metal resistance genes (Tables S11, S12, S13). Notably, the genomes contain homologs to genes known to specify resistance to arsenate, cadmium, and mercury. All three genomes contained arsenate detoxification genes, *arsC*, *arsR*, *ACR3*, and arsenate respiration genes (Tables S8, S9). P-type ATPases encoding for the efflux of mono- (P_{1B-1} -ATPases) and di-valent (P_{1B-2} -ATPases) cations (Smith et al., 2014) were identified among all three genomes. *Vibrio* spp. T9 and T21 contained P_{1B-1} -ATPases (2 copies) and P_{1B-2} -ATPase (1), while *Shewanella* sp. BC20 contained only P_{1B-1} -ATPases (2) (Table S10) possibly explaining why the *Vibrio* spp. were resistant to cadmium, while *Shewanella* sp. BC20 was sensitive. Interestingly, in *Vibrio* sp. T21, one of the P_{1B-1} -ATPases was located on a predicted genomic island (Fig. 1B).

5. Conclusions

In summary, the co-occurrence of multiple antibiotic and metal resistances in three coastal bacterial isolates adds to numerous reports (e.g., Pal et al., 2017; Henriques et al., 2016)). Coastal marine environments are zones where high microbial productivity, anthropogenic contaminants, and high human population density may converge to create a hot spot for the selection of ARGs and their subsequent inheritance among bacteria.

Our results have implications in both the environment and clinic. Some of the resistance gene homologs identified here were previously shown to occur in human pathogens. Our results provide information on the antibiotic and metal resistome of three strains isolated from the mummichog intestinal microbial community, a potential reservoir of ARGs, and opportunistic human pathogens including *Vibrio parahaemolyticus* and *Shewanella* spp. Our findings contribute to the understanding of the mechanisms underlying co-selection in the environment and can also be used to assess the threat of potential emerging zoonotic infections, as well as predict the composition of the resistant community in the environment.
