ABSTRACT

In this communication, we address the problem of unsupervised dimensionality reduction (DR) for hyperspectral images (HSIs), using nearest-neighbor density-based (NN-DB) approaches. Dimensionality reduction is an important tool in the HSI processing chain, aimed at reducing the high redundancy among the HSI spectral bands, while preserving the maximum amount of relevant information for further processing. Basically, the idea is to formalize DR as the process of partitioning the spectral bands into coherent band sets. Two DR schemes can be set up directly, one based on band selection, and the other one based on band averaging. Another scheme is proposed here, based on compact band averaging. Experiments are conducted with hyperspectral images composed of an AISA Eagle HSI issued from our acquisition platform, and the AVIRIS *Salinas* HSI. We evaluate the efficiency of the reduced HSIs for final classification results under the three schemes, and compare them to the classification results without reduction. We show that despite a high dimensionality reduction ($< 8\%$ of the bands left), the clustering results provided by NN-DB methods remain comparable to the ones obtained without DR, especially for GWENN in the band averaging case. We also compare the classification results obtained after applying other unsupervised or semi-supervised DR schemes, based either on band selection or band averaging, and show the superiority of the proposed DR scheme.

Keywords: Dimensionality reduction, clustering, hyperspectral image, nearest neighbor, density estimation.

1. INTRODUCTION

Dimensionality reduction (DR) is an important tool in the hyperspectral image (HSI) processing chain. Indeed, DR is aimed at reducing the high redundancy which can be observed between spectral bands, and therefore can be useful to eliminate the most redundant bands while preserving the most informative ones. DR is highly desirable since it summarizes the informational content with minimum impact on the further processing tasks such as pixel classification, therefore allowing a considerable gain in data storage and processing.

In this communication, we address the problem of unsupervised DR for HSIs, using nearest-neighbor density-based (NN-DB) approaches. NN-DB methods are initially automatic classification methods designed to partition data objects without specifying neither the number of clusters to be found nor learning samples. In this sense they are different from the state of the art K-Means and FCM clustering methods. Moreover, they are deterministic, very simple to implement, and some of them are non iterative. Among the NN-DB approaches one can cite ModeSeek,¹ knnDPC,^{2,3} knnClust,⁴ and GWENN-WM (Graph WatershEd using Nearest Neighbors with Weighted Mode).^{2,5}

The present work studies the applicability of NN-DB methods to DR, which is seen as a processing task previous to clustering. More precisely, considering the fact that NN-DB methods (like other clustering methods) automatically provide exemplar objects which are representative of the clusters, and due to its good performances

in clustering, we investigate the potential of GWENN and other NN-DB methods to reduce the dimensionality of HSIs by performing band clustering in an unsupervised manner.

The paper is organized as follows: in Section 2, we provide an overview of related works in the field of dimensionality reduction focusing on HSIs, and point out the need for unsupervised approaches which do not constraint the user to specify the number of retained bands; in Section 3, we detail the implementation of NN-DB methods in the HSI processing chain, and provide improvements of the baseline selection of band exemplars; Section 4 describes an experimental study of the proposed scheme, involving two HSIs, namely an AISA Eagle HSI acquired by our hyperspectral platform in the framework of a study on seashore algae habitats, and the AVIRIS *Salinas* HSI; we conclude in Section 5.

2. RELATION TO PREVIOUS WORKS AND MOTIVATION

In a recent work,² a set of nearest-neighbor density-based clustering methods was proposed and compared in the context of large scale hyperspectral image pixel partitioning. The conclusions of this work were that NN-DB methods are interesting alternatives to a classical (semi-supervised) clustering methods such as fuzzy c-means (FCM), providing results which are faster, more efficient in terms of classification accuracy, and deterministic. These methods only rely on the computation of a nearest neighbor (NN) graph from the original data set, obtained by a greedy NN search procedure. This graph is governed by a single parameter k , i.e. the number of nearest neighbors (NNs) which is set by the user. Also, a model of local (point-wise) density is adopted in Ref. 2, still depending on the same parameter k :

$$\rho(\mathbf{x}_m) \propto \frac{k}{\sum_{\mathbf{x}_j \in k\text{NN}(\mathbf{x}_m)} d(\mathbf{x}_m, \mathbf{x}_j)} \quad , \quad 1 \leq m \leq N, \quad (1)$$

where N is the number of objects, and $k\text{NN}(\mathbf{x}_m)$ is the set of nearest neighbors to $\mathbf{x}_m$ according to the Euclidean distance $d(\cdot, \cdot)$. Using the $k\text{NN}$ graph and the density model above, the four NN-DB methods described in Ref. 2, represent different partitioning strategies by aggregation of objects based on the interaction between NNs' local densities. These approaches have two important features: the first one is that they do not require the explicit knowledge of the number of clusters which form the partition, and the second one is the stability of the number of clusters with respect to k around the optimal working point. Similar examples of adaptation of initial clustering methods to HSI DR have been proposed in the literature. For example a refinement of the the K-Means algorithm has been shown to provide superior classification accuracy than similar band reduction methods.⁶ In this case the extracted bands are chosen as the centers of the band clusters. However, this approach is still semi-supervised since it requires the user to specify the number of bands to retain. Actually, few unsupervised methods derived from clustering exist which automatically outputs some optimal number of bands. Of course the classical principal component analysis (PCA) is able to provide a reduced representation of the original data by projecting it onto subspaces with greater projected data variances. But, in its baseline implementation, PCA implies that the extracted bands are linear combinations of the original bands, not necessarily accounting for their relative spectral position and adjacency. One interesting implementation of band selection by clustering was proposed in Qian et al.⁷ Their method is based on Affinity Propagation (AP),⁸ which requires no critical parameter to work and is able to provide an optimal number of clusters by maximizing a criterion involving the sum of 'responsibilities' and 'availabilities'. In the context of HSI DR, AP produces a set of so-called *exemplar bands* which are the most representative of the whole band set. In essence, the exemplar bands play the same role as the centers of the band clusters in Ref. 6. More recently, following the work of Rodriguez and Laio⁹ on density-based clustering, Tang et al.¹⁰ proposed a method, called FDPC (Fast Density Peak Clustering) for unsupervised band selection. The two latter methods were found to be more efficient in terms of classification accuracy than other band selection techniques, including Information Divergence (ID)¹¹ and Maximum Variance PCA (MVPCA).¹²

The unsupervised band selection methods cited above provide, via the band exemplars, an optimal subset of individual bands which best represent the subbands formed owing to the clustering procedure. An alternative way is to summarize the spectral information by *averaging* the bands found in each subband. Averaging has two positive effects: (i) the whole spectral content is accounted for; (ii) one might expect noise reduction. In addition, averaging spectrally neighboring bands is physically relevant. These points have been crucial in the

proposition of an unsupervised mutual-information based called BandClust,¹³ which automatically provides an optimal number of bands from averaged neighboring bands.

The motivation behind the present work is to evaluate the reliability of NN-DB methods (especially GWENN) when used to cluster spectral bands (instead of objects) efficiently, and to compare this approach with similar DR methods. Another indirect objective is to evaluate the difference in DR relevance between band selection (as directly offered by band exemplars) and band averaging (as an alternative way to summarize the spectral information).

3. NN-DB DIMENSIONALITY REDUCTION BY BAND CLUSTERING

In this section we detail the different approaches proposed to perform DR on HSIs based on NN-DB band clustering. The first one is a band selection method based on band exemplars issued from the clustering procedure; the second one relies on band averaging using the band clusters outputted; the third one introduces a constraint to insure the spectral compactness of the retained bands, before averaging.

3.1 Exemplar band selection

Let a hyperspectral image be rearranged (thanks to image row or column stacking) as a collection $\mathbf{X} = \{\mathbf{x}_i = [x_i(1), \dots, x_i(N)]\}_{i=1, \dots, B}$ of N -dimensional vectors, where N is the number of pixels in the HSI, and B is the original number of spectral bands (or features). It is important to notice here that, despite the potentially high number of spectral bands B , we still assume $B \ll N$, so that the dimensionality of the vectors is very high.

The principle of band clustering consists in grouping the spectral bands $\{\mathbf{x}_i\}_{i=1, \dots, B}$ into coherent clusters, without much prior information. NN-DB approaches to band clustering are based upon the availability of a k -nearest neighbor (k NN) graph, i.e. for each spectral band the set of the k closest bands (w.r.t. some distance metric), ordered by ascending distance. The choice of the metric can be of importance due to the high dimensionality of the representation space. However, we have not further investigated this issue, and simply used the Euclidean distance $d(\mathbf{x}_i, \mathbf{x}_j) = \|\mathbf{x}_i - \mathbf{x}_j\|_2$ throughout this work.

The implementation of NN-DB methods to HSI DR is rather straightforward, and basically consists of applying the clustering method to the transposed array of original data: each band $\mathbf{x}_i$ is an object (rather than a feature), and must belong to one and only one band cluster. NN-DB methods also require to compute a local density for each band from its neighboring bands. In the present work, we propose to replace the density model stated in Eq. 1 by the following one:

$$\rho(\mathbf{x}_m) \propto \sum_{\mathbf{x}_j \in k\text{NN}(\mathbf{x}_m)} d^{-1}(\mathbf{x}_m, \mathbf{x}_j) \quad , \quad 1 \leq m \leq B. \quad (2)$$

This choice appears to provide better results than the one in Eq. 1 in terms of classification accuracy and therefore has been retained in our experiments.

NN-DB methods were described in Ref. 2, with four methods compared: ModeSeek, knnDPC, knnClust-WM, and GWENN-WM. Due to space limitation, we provide only the DR version of GWENN-WM in Algorithm 1. Contrarily to the three other ones, this algorithm is non iterative and therefore has fully controlled complexity. `wmode` is a function computing the class label of the current band m based on the labels of its nearest neighbors (in $\mathbb{R}^N$) as well as their respective densities. Note that an additional loop traversing the spectral bands has been added w.r.t. Ref. 2, which helps stabilizing the formed clusters by merging isolated bands into existing band clusters. The band exemplars issued from the algorithm are expected to be the most representative of the whole HSI.

Algorithm 1 GWENN-WM-DR

Require:

$\mathbf{X} = \{\mathbf{x}_m\}, \mathbf{x}_m \in \mathbb{R}^N, m = 1, \dots, B$; % The set of spectral bands to cluster
 k , the number of NNs;

Ensure: The vector of bands' labels $\mathbf{c} = [c_1, \dots, c_B]^t$; the set of band exemplars $\mathcal{E}$;

- 1) Compute $\mathbf{D}$, the $B \times k$ array of distances (in ascending order) between each band and its k NNs.
- 2) Compute $\mathbf{J} = \{\mathbf{j}_m\}_{m=1, \dots, B}, \mathbf{j}_m = [j_m^1, j_m^2, \dots, j_m^k]$, the $B \times k$ array of indices of each object's k NNs.
- 3) Compute the pointwise densities $\{\rho(m)\}_{m=1, \dots, B}$ following Eq. (2).
- 4) Compute $\rho' = \text{DescendSort}(\rho)$, keep k NNs indices $\mathbf{i} = [i_1, i_2, \dots, i_M]^t : \rho' = \rho(\mathbf{i})$.
- 5) $NC = 1$; % NC is the current number of band clusters

$c_{i_1} = NC$; % The "denser" band takes the first label

$\mathcal{E} = \{i_1\}$; % The set of band exemplars is initialized with the index of the denser band

$P = \emptyset$;

for $m = 2 : B$ **do** % First, main pass

$P \leftarrow P \cup i_{m-1}$;

$Q = P \cap \mathbf{j}_{i_m}$;

if $Q \neq \emptyset$ **then**

$c_{i_m} = \text{wmode}(\mathbf{c}_Q, \rho_Q)$;

else

$NC = NC + 1$;

$c_{i_m} = NC$;

$\mathcal{E} \leftarrow \mathcal{E} \cup \{i_m\}$; % Add i_m to the set of band exemplars

end if

end for

$\mathbf{c}' = \mathbf{c}$;

for $m = 1 : B$ **do** % Second, refinement pass

$Q = \mathbf{j}_m$;

$c'_m = \text{wmode}(\mathbf{c}_Q, \rho_Q)$;

end for

$\mathbf{c} = \mathbf{c}'$;

3.2 Band averaging

In the above scheme, DR is performed by simple band selection based on the band exemplars found by NN-DB methods. Following Vermillion et al.,¹⁴ narrow bands are not necessarily the best choice, and larger bandwidths can increase the signal to noise ratio. Band averaging has been promoted in Belluco et al.¹⁵ as an effective feature reduction method. In Ref 13, band averaging has been shown to provide superior results compared to some semi-supervised band selection methods.

Therefore, in the present work, since NN-DB methods (like other band clustering methods) end up with coherent groups of bands, the natural way to perform band averaging is to compute the mean of the bands within each formed cluster, i.e. of the bands having identical label $c_l, 1 \leq l \leq NC$, where NC is the number of band clusters.

3.3 Band averaging with compactness constraint

As such, band clustering does not guarantee that the band partitions only contain spectrally neighboring bands, i.e. bands which are spectrally adjacent. This is why it can be useful to modify the NN-DB methods to avoid merging spectrally distant bands into the same band cluster, therefore preserving the physical nature of hyperspectral image formation.

To tackle this problem, we propose here a simple approach which can avoid the above problem. The idea is to modify the k -NN graph such as to exclude, from the nearest neighbor bands of one specific band, those which are located outside a given spectral interval around the latter. Figure 1 illustrates how the set of NN bands of a

given band $\mathbf{x}_m$ is modified: consider the (compact) set of contiguous spectral bands $[\mathbf{x}_{m-l}, \mathbf{x}_{m+l}]$ (black dots), and $k\text{NN}(\mathbf{x}_m)$ the set of NN bands found by the NN search (blue dots). Then the NN-DB methods will use as the modified NNs the set intersection of the latter, i.e.:

$$k\text{NN}'(\mathbf{x}_m) = [\mathbf{x}_{m-l}, \mathbf{x}_{m+l}] \cap k\text{NN}(\mathbf{x}_m) \quad , \quad 1 \leq m \leq B. \quad (3)$$

Since $|k\text{NN}'| \leq |k\text{NN}|$ the computation of the density in Eq. (2) is adjusted in consequence. This constrained NN band clustering scheme insures that the band clusters created by the NN-DB methods are compact on the ordered set of spectral bands. One disadvantage of this approach is that it requires an additional parameter, l , governing the 'spectral scope' around the current band. We found in our experiments that taking $l = k$ is a fairly efficient choice, thereby reducing the parametrization to the sole value of k .

Figure 1. Illustration of constrained NN band subsetting prior to NN-DB HSI DR ($k = 7, l = 3$).

In the following, the DR versions of GWENN-WM will be named GWENN-DR.

4. EXPERIMENTAL STUDY

4.1 Experiment 1: *Salinas* HSI

In this experiment, we analyzed the potential use of one NN-DB method, namely GWENN-DR (with weighted mode) to perform efficient band reduction on a popular (and well conditioned) benchmark image. To this end, we selected the *Salinas* HSI*. This image was acquired by the AVIRIS sensor in 1998 over agricultural fields. It has a spatial size of 512×217 pixels, and 204 spectral bands. The reference map is composed of 16 vegetation classes as shown on Figure 2. This map was used for assessing the clustering results in terms of classification accuracy, following the procedure described in Ref. 16 to best align unsupervised classification results with ground truth data. After careful examination of the spectral signatures in this HSI, we found that four pixels were spectrally altered by some unknown effect (at spatial locations (131, 132), (131, 133), (500, 51) and (500, 52)), and thus we have rejected them as outliers.

The experiment was designed to compare GWENN-DR methods with other band clustering methods as well as other state of the art DR methods. For each method, the HSI is first processed for DR; then the reduced HSI undergoes an unsupervised clustering step; finally the clustering result is evaluated owing to the reference map. The choice of the clustering method to be applied after DR was guided by the willing to keep the processing chain as much unsupervised as possible. This is why we have also selected NN-DB clustering methods (and more particularly GWENN) due to their interesting performances.² Note that in this experiment, and differently to our previous works, we did not use here any multiresolution analysis scheme to accelerate the clustering stage. Instead, a full $k\text{NN}$ graph (with $k \leq 3000$, i.e. less than 3% of the number of objects) was computed over the whole HSI (111104 objects).

4.1.1 Dimensionality reduction

Before applying the DR stage, each spectral band of the original *Salinas* HSI was normalized to zero mean and unit variance. This step was found to provide better results in terms of classification accuracy at the end of the processing chain, w.r.t. no normalization (i.e. original data).

*http://www.ehu.es/ccwintco/index.php?title=Hyperspectral_Remote_Sensing_Scenes

We first applied GWENN-DR to the normalized HSI. For this, we used $k = 5$ in Algorithm 1, which provided 15 band clusters. At this point, two DR results can be produced, i.e. a band selection (*BSel*) result based on the band exemplars found by GWENN-DR, and a band averaging (*BAvg*) result based on the means of each band cluster, each result consisting of 15 bands. Then we applied three NN-DB methods, namely ModeSeek, knnDPC and GWENN-WM to both reduced images as well as to the original HSI (204 bands). Figure 3 displays three classification performance indices, namely the Average Correct Classification Rate (ACCR), the Overall Correct Classification Rate (OCCR), and the kappa index of agreement as a function of the number of NNs k used in the NN-DB clustering stage. These curves appeal several comments. Firstly, it can be observed a differentiated behavior in average performance indices between *BSel* and *BAvg*, on both the quality of the clustering result (higher for *BAvg*) and on the number of NNs required to reach the optimum clustering (higher for *BSel*). Hence in average, it appears at least experimentally that band averaging should be preferred to band selection whatever the NN-DB used. Secondly, ModeSeek seems less efficient than knnDPC or GWENN-WM in average on the DR image, and this is also true for the original HSI. Lastly, one can see that knnDPC and GWENN-WM are able to provide classification performance indices which can locally fairly compare with the ones obtained from the original HSI; for instance, the OCCR and kappa indices of GWENN-WM applied to GWENN-DR image after *BAvg* are less than 2.8% lower than the maximum ones obtained by applying GWENN-WM on the original HSI. Therefore one can conclude that GWENN-DR with band averaging is appropriate for HSI dimensionality reduction.

4.1.2 Comparison with other DR methods

Here, we selected GWENN-WM as the only classifier, whereas we applied to it the results of several DR methods. These include a semi-supervised band selection method (LP/OSP¹⁷) where the number of selected bands is specified by the user, an unsupervised band averaging based on AP,^{7,8} and an unsupervised band averaging method (BandClust¹³). We also included the results issued from the third band grouping strategy discussed in 3.3, which we called *CBAvg*, standing for compact band averaging.

In order to verify and compare the spectral coherence of the band clustering schemes, we show in Figure 4 the location of the band clusters, exemplars or selection subsets given by the above methods. For GWENN-DR, one can see that, except for the lowest and highest bands, most band exemplars found by GWENN-*BSel* are located near the center of their corresponding band cluster in GWENN-*BAvg*. However, some of the band clusters formed for the latter are non compact, especially between bands 40 and 80. As expected, the situation is better for GWENN-*CBAvg*, for which the band clusters are strictly compact over the spectral range. BandClust also provides compact sub-bands (this is normal since it is a band splitting algorithm) which slightly differ from the previous ones. Specifically, the red edge¹⁸ (bands 34-41) is clearly identified as a cluster, whereas only the inflection point of the red edge is marked as a singleton cluster by GWENN-*CBAvg*. However, the number of sub-bands found automatically by BandClust (14) is very close to the one obtained with the GWENN-DR approaches. Comparatively, the LP/OSP and the AP-*BAvg* methods exhibit lesser coherence in the band selection or band clusters outputted.

Figure 5 displays the classification performance indices as above, where the previous curves of GWENN-DR with *BSel* and *BAvg* are reported again together with the other studied methods. Among the DR methods, GWENN-*CBAvg* achieves superior clustering performances and stability than GWENN-*BAvg* and BandClust for $k \geq 1800$ (highest OCCR: 73.52% at $k = 1800$). The BandClust DR result provides overall efficient clustering. Besides, LP/OSP (*BSel*) is inferior to GWENN-*BSel* for all values of k in the clustering stage. Finally, AP provides poor results, despite it is here a band averaging method. For the two latter methods, these results are in agreement with the previous observations regarding the location of the band clusters and selection subsets.

4.2 Experiment 2: Classification of foreshore algae species

We present here an application of the proposed DR to a larger HSI. Similarly as above, DR is followed by unsupervised clustering using GWENN-WM with the density estimation proposed in Eq. (2). The difference here relies in the way we manage the size of the HSI; for this we used the multiresolution scheme proposed in Ref. 2.

The HSI has been acquired on June 13, 2014 by our hyperspectral imager (AISA Eagle) mounted on an aircraft over the region near the city of Veulettes-sur-Mer, Normandy, France. The objective of the aerial survey was the

identification of algae species and substrates. A number of regions were identified at the ground level as relatively homogeneous (despite the high complexity of the foreshore coverage), which were reported to produce a ground truth (GT) map with ten classes (6608 pixels). Figure 6 displays a RGB view of the HSI with superimposed GT map. The size of the image cube is (1264×592) pixels $\times$ 126 bands.

In this experiment, we selected for comparison two NN-DB DR methods, i.e. GWENN-BAvg and GWENN-CBAvg, as well as BandClust and AP-DR. The reduced HSIs, as well as the original (full bands) HSI then entered the same clustering procedure, i.e. GWENN-WM, with varying number of NNs k as above, and a 4-level resolution. The advantage of using GWENN-WM is its capability to stabilize the number of exemplars from one scale resolution to the others.² As above, ACCR, OCCR and kappa indices were calculated for evaluation.

Figure 8 shows the comparison of clustering performance indices for k in the range $[20, 40]$. Due to the complexity of the foreshore environment, with numerous mixtures of substrates, algae species and presence of water in more or less large puddles, it is not surprising that the classification indices are lower in average than in the previous experiment. However, it can be seen that GWENN-CBAvg is able to reach the highest OCCR and kappa indices among the other DR methods, for $k = 36$. We show in Figure 7 the corresponding clustering result. Twelve different classes have been found among the pixels of the ground truth, whereas the total number of clusters is 19. One important point in this experiment is the observation that DR is able to provide a reduced band set which is more relevant for further clustering than the original HSI with 126 bands.

5. CONCLUSION

In this paper, we have proposed the use of nearest-neighbor density-based clustering approaches to spectral band grouping in the context of dimensionality reduction (DR) for hyperspectral images. More precisely, we have investigated three DR strategies, i.e. band selection based on band cluster exemplars directly issued from the band clustering procedure, then the averaging of bands belonging to each cluster, and finally a constrained band averaging scheme aiming to preserve the spectral compactness within each form band cluster. Experiments with a popular benchmark HSI and on a HSI acquired by our AISA Eagle hyperspectral acquisition platform allow us to conclude on the effectiveness of NN-DB clustering-based DR with respect to other unsupervised or semi-supervised methods like LP/OSP and AP. Beyond these observations, the experimental results in the present work also confirm the superiority of the band averaging principle to summarize the spectral information, with respect to simple band selection.

Figure 6. AISA Eagle HSI (Color composite, bands 57, 36, 14) and superimposed ground truth map.

Figure 7. Best clustering result among the selected unsupervised methods, in terms of OCCR and kappa index, and obtained after DR with GWENN-*CBAvg*.

Figure 8. *AISA Eagle* HSI: Comparison of GWENN-WM classification results after applying several DR methods. Top: Average correct classification rate (ACCR); middle: Overall correct classification rate (OCCR); bottom: Kappa index.
