Abstract: The formation of the ternary Pt₃NiAu and Pt₃CuAu nanostructures are examined using molecular dynamics simulations in the context of free (i.e. unsupported) cluster growth in an unreactive atmosphere. The role of Au segregation towards the cluster surface on the final composition and structure of the nanoparticles is highlighted, as well as the effect of temperature on the growth and structure of the ternary nanocatalysts. Indeed, while a Pt₃NiAu nanoparticle consisted in core of Pt₃Ni alloy surrounded by an Au sub-monolayer, a Pt₃CuAu particle consisted in a Pt_xCu core alloy ($x < 3$) surrounded by a sub-monolayer of AuCu alloy. The predicted atomic structures are enlightening the experimental results obtained from low temperature syntheses of ternary nanomaterials and their electrochemical behaviors.

Keywords: Fuel cell nanocatalyst; molecular dynamics; plasma sputtering; electrochemical characterization

1. Introduction

The activation of oxygen is of paramount importance for electrocatalytic processes in general and for fuel cells in particular to make this technology marketable. Because the oxygen reduction reaction (ORR) is occurring at the cathode of fuel cells with very low kinetics, it has been extensively studied for the last fifty years with the aim at enhancing the catalyst and cathode efficiencies [1]. Controlling the metal nanoparticle growth is essential for improving particle size distribution, structure, morphology and, in the case of multi-metallic catalysts, surface composition to further achieve high activity and selectivity. To obtain this control, the understanding of the nanoparticle growth mechanism is a prerequisite.

It is indeed known that platinum-based ternary alloys are excellent catalysts for the electro-reduction reaction of oxygen molecule, which occurs at the cathode of a PEMFC (proton exchange membrane fuel cell) [2-10]. Beyond the lowering of the platinum loading in the electrode catalytic layers, alloyed Pt-based materials display an improved catalytic activity towards the ORR [11], a better tolerance towards poisoning species [12,13] and, for some authors, an enhanced durability under fuel cell working conditions [14]. Addition of Au was indeed proposed to improve the durability of Pt-based nanocatalysts [14-23]. Nevertheless, only few fundamental studies on such kind of catalysts are available.

The present work aims at calculating and discussing the growth mechanism of such ternary catalysts in order to predict their compositions and morphologies for direct comparison with nanocatalysts synthesized by classical low temperature methods (wet chemistry or low temperature plasma deposition). This dynamical point of view is intended to unravel the variety (or not) of the generated nanoclusters and to clarify the link between nanocluster composition, structure, morphology and electrochemical behaviors.

To this end, molecular dynamics (MD) simulations are suitable ways for addressing the growth mechanism of nanoclusters, and especially nanocatalysts [24]. This simulation method consists in calculating all the trajectories in a group of interacting atoms with only a restricted number of assumptions: only the interaction forces and a set of initial conditions preferably matching the experimental conditions are required.

In a previous work, we have been able to link results from DFT calculations and MD simulations concerning the growth and structure of ternary catalysts based only on noble metals ($\text{Pt}_x\text{Pd}_y\text{Au}_z$ materials) [20]. In the present work, molecular dynamics simulations will be used to predict the growth mechanism and the final structure of Pt_3Me and Pt_3AuMe catalysts, where Me corresponds to a non-noble metal. Indeed, there is no evidence that same results could be *a priori* obtained by replacing a noble metal (Pd) by a non-noble one. The formations of ternary Pt_3NiAu and Pt_3CuAu materials are considered since they are well documented. Pt_3Ni , as a base bimetallic alloy [25-28], and Pt_3NiAu ternary system [21] exhibit very high initial electrocatalytic activity towards the ORR, whereas Pt_3CuAu ternary system displays higher stability [21].

Section 2 will present the simulation method and describe the chosen parameters, while section 3 will present, compare and discuss molecular dynamics results in light of experimental ones, with a special focus on electrochemical results in terms of activity towards ORR and surface nanoparticles composition changes with ageing. [22].

2. Methods

For simulating free (i.e. unsupported) clustering, atoms are randomly distributed in a cubic box with atomic ratios corresponding to the targeted composition. A neutral gas buffer is added for describing the energy dissipation during collisions. This is mimicking free nanoparticle growth in the context of a gas aggregation source (GAS) where atoms are

sputtered in such a gas at a pressure high enough for allowing clustering in the flight [29-33]. This approach is also likely mimicking the nanoparticle growth in a liquid, as it is the case for wet chemistry synthesis such as the “water in oil” microemulsion method, where the reaction takes place in water nanodroplets containing the metal salts in concentrations corresponding to the targeted compositions of nanoparticles. In this latter case, the ratio between the metal atom number and the liquid molecule number is smaller than the ratio between the metal atom number and the gas atom number in the case of simulation experiment.

In the present work, the atomic vapor consists in Pt, Au and Me (Ni or Cu) atoms or Pt and Me (Ni or Cu) immersed in an Argon bath, dedicated to the dilution of metal atoms and to the dissipation of the energy generated during bond formation. The simulation box has a size of $64 \times 64 \times 64 \text{ nm}^3$ and is filled with $N_{\text{Ar}} = 128000$, $N_{\text{Pt}} = 19200$, $N_{\text{Me}} = 6400$ and $N_{\text{Au}} = 6400$ atoms. Periodic boundary conditions are applied in the x, y, z directions. Initial temperature is 300 K. The equations of motion used for describing the clustering process is:

$$\frac{\partial^2 \vec{r}_i(t)}{\partial t^2} = \frac{1}{m_i} \vec{f}_i, \quad \text{with the force } \vec{f}_i = -\frac{\partial}{\partial \vec{r}} V(\vec{r}_1(t), \vec{r}_2(t), \dots, \vec{r}_N(t)) \quad (1)$$

where $\vec{r}_i(t)$ is the instantaneous position of atom i with mass m_i at time t , and V is the interaction potential function.

Embedded Atom Model (EAM) potential functions [34-36] are suitable for describing metal atom interactions, i.e. Pt, Me (Ni or Cu) and Au in the present case. The EAM potential is a many-body potential which is including the collective motions of electrons. Essentially, each atom contributes to the overall charge density of the system, via a spherical electron charge, centered at its nucleus. The binding between atoms is modelled considering that these atoms are embedded in this “pool” of charge, where the energy gained by embedding an atom at location r is a function of the local electron density.

The EAM potential energy E_{pot} of the system thus reads as:

$$E_{pot} = \sum_{i=1}^N E_i = \frac{1}{2} \sum_{i=1}^N \sum_{j,j \neq i}^N \varphi_{ij}(r_{ij}) + \sum_{i=1}^N F_i(\rho_i) \quad (2)$$

where E_i is the potential energy of an atom i , $\varphi(r_{ij})$ is the pair energy term as a function of the interatomic separation r_{ij} between atoms i and j , and $F_i(\rho_i)$ is the many-body embedding energy term, function of the local electron density, ρ_i , at the position of atom i .

The local electron density is calculated as:

$$\rho_i = \sum_{j,j \neq i}^N f_j(r_{ij}) \quad (3)$$

where $f_j(r_{ij})$ is the contribution from atom j to the electron density at the site of the atom i .

The pair potential energy term is defined as:

$$\varphi(r) = \frac{A \exp\left[-\alpha\left(\frac{r}{r_e}-1\right)\right]}{1+\left(\frac{r}{r_e}-\kappa\right)^{20}} - \frac{B \exp\left[-\beta\left(\frac{r}{r_e}-1\right)\right]}{1+\left(\frac{r}{r_e}-\lambda\right)^{20}} \quad (4)$$

where r_e is the equilibrium spacing between nearest neighbors, A , B , α , and β are four adjustable parameters, and κ and λ are two additional parameters for the cutoff distances [35, 36]. The electron density function is taken to have the same form as the attractive term in the pair potential with the same values.

The electron density function is given by:

$$f(r) = \frac{f_e \exp\left[-\beta\left(\frac{r}{r_e}-1\right)\right]}{1+\left(\frac{r}{r_e}-\lambda\right)^{20}} \quad (5)$$

The pair potential between atoms of two different elements (a and b) is built using the mixing rule [37]:

$$\varphi^{ab}(r) = \frac{1}{2} \left[\frac{f^b(r)}{f^a(r)} \varphi^{aa}(r) + \frac{f^a(r)}{f^b(r)} \varphi^{bb}(r) \right] \quad (6)$$

The embedding energy function $F(\rho)$ is represented by three equations defining it in different electron density ranges and having matching values and slopes at the two junctions:

$$F(\rho) = \sum_{i=0}^3 F_{ni} \left(\frac{\rho}{0.85\rho_e} - 1 \right)^i, \quad \rho < 0.85\rho_e \quad (7)$$

$$F(\rho) = \sum_{i=0}^3 F_i \left(\frac{\rho}{\rho_e} - 1 \right)^i, \quad 0.85\rho_e \leq \rho < 1.15\rho_e \quad (8)$$

$$F(\rho) = F_e \left[1 - \eta \ln \left(\frac{\rho}{\rho_e} \right) \right] \times \left(\frac{\rho}{\rho_e} \right)^\eta, \quad \rho \geq 1.15\rho_e \quad (9)$$

where η , F_i , F_{ni} , F_e , ρ_e are adjustable EAM parameters [35, 36].

Ar atoms are interacting with metal atoms through repulsive Molière potentials [38]. Initial velocities of all atoms are sampled from a Maxwell-Boltzmann distribution at 300 K. Calculations consider a constant number of metal atoms, constant volume and constant total energy (NVE ensemble). This allows calculating the interaction between metal atoms without any constraints. NVT ensemble (for which the temperature of Ar atoms is maintained constant) calculation is chosen for mimicking cluster cooling via Ar collisions on clusters, as it occurs in experiments. The time step for integrating the equation (1) is set to 1 fs and 40 ns total simulated time. Simulations have been carried out using the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) [39,40] and visualization using the Visual Molecular Dynamics (VMD) program [41,42].

3. Results

3.1 Pt₃Ni (+Au) growth

Figure 1a,c (full simulation box) display the snapshots from the simulations for the Pt₃NiAu free nanocatalyst growth at 20 ns and 40 ns simulation time, respectively, when the cluster coalescence is already well advanced. Two typical sizes are observed in Figure 1a, and this is confirmed by the corresponding nearly bimodal size distribution presented in Figure 1b. The two cluster families have mean diameters of 1.8 and 3.0 nm indicating that coalescence of smaller clusters with similar size has already started. At the latter step (40 ns), the cluster

density is low enough for avoiding further significant coalescence of clusters. The size distribution remains bimodal, is broadened and shifted to larger sizes. The two cluster families are centered at diameters of 2.6 and 3.8 nm, respectively.

Figure 1: Snapshots of Pt₃NiAu at different simulation times a) t = 20 ns and c) at t = 40 ns. The corresponding size distributions are reported in graphs b) and d). Pt atoms are blue, Ni atoms brown, and Au atoms pink. Argon atoms are not displayed for clarity. Colors only online.

It is clearly visible that Au atoms predominantly cover the nanoparticle surface, indicating the Au segregation towards surface is a major mechanism for the growth of such multi-metallic catalysts. For comparison, Figure 2 displays Pt₃Ni snapshots and corresponding

diameter distributions for $t = 20$ ns (Figure 2a,b) and 40 ns (Figure 2c,d) simulation times. In the case of Pt_3Ni cluster growth simulation, the simulations conditions considers a box with a size of $64 \times 64 \times 64 \text{ nm}^3$ filled with $N_{\text{Ar}} = 128000$, $N_{\text{Pt}} = 19200$, $N_{\text{Ni}} = 6400$.

Figure 2: Snapshots of Pt_3Ni at different simulation times a) $t = 20$ ns and c) at $t = 40$ ns. The corresponding size distributions are reported in graphs b) and d). Pt atoms are blue and Ni atoms brown. Argon atoms are not displayed for clarity. Colors only online.

Figure 2 shows that the growth of Pt_3Ni clusters is very similar to that of the Pt_3NiAu ones. Nevertheless the size distribution at 20 ns appears narrower for Pt_3Ni than for Pt_3NiAu . When looking to the change of the mean diameter with respect to time (Figure 3), the Pt_3Ni mean

diameter is always slightly smaller than that of Pt_3NiAu . The difference comes from the additional Au atoms (25 % more atoms in the initial vapor compared with the case of Pt_3Ni) leading to larger particles and also to the different numbers of clusters formed. Indeed, less metal atoms are involved in the Pt_3Ni cluster growth simulation than in the Pt_3NiAu cluster growth simulation, therefore, there is no reason for the number of clusters formed at a given time to be the same in both cases. The similar diameter values at 40 ns can originate from lower statistics since the growth and then the coalescence of clusters involves a decrease of their number with time. The size distributions of Pt_3NiAu and Pt_3Ni clusters for calculating the mean diameters at different simulation times are given in supplementary information (Figure S1).

Figure 3: Pt₃Ni (◆) and Pt₃NiAu (●) cluster mean diameters along simulation time. The error bars are calculated assuming the error comes from cluster statistics. The decrease of cluster number for larger times implies higher uncertainty (larger error bars). Color only online

The progress of the cluster coalescence process at 40 ns is depicted in Figure 4b for $t = 40$ ns, where the proportion of small clusters has decreased in comparison with that in Figure 1a. The histogram presented in Figure 1d shows a shift towards higher cluster sizes and a broadening of the corresponding size distribution. Due to coalescence, clusters present first peanut-like shapes in the early stage of coalescence, and evolve towards spherical shapes further into the coalescence process.

Figure 4: Zoomed snapshots of Pt₃NiAu at a) t = 20ns, b) at t = 40 ns. Cross section of typical clusters at c) t = 20 ns and d) t = 40 ns. A well and a less crystallized clusters are displayed. Pt atoms are blue, Ni brown, and Au pink. Argon atoms are not displayed for clarity. Colors only online.

Pt₃NiAu clusters at 20 ns mainly exhibit spherical not fully crystallized clusters (Figure 4a). Au atoms are only present on the surface (Figure 4c) and do not fully cover the nanoparticle surface leaving open access to the core catalytic sites.

Figure 4b provides a zoom at 40 ns. The clusters have mainly kept their spherical shape during coalescence. Some of them (not shown on Figure 4b) have a peanut shape. Looking at the clusters cross-section (Figure 4d), the peanut shaped nanoparticles exhibit a well crystallized core while spherical ones remains not fully crystallized.

Figure 5: Zoomed snapshots of Pt₃Ni at a) $t = 20$ ns, b) at $t = 40$ ns. Cross section of typical clusters at c) $t = 20$ ns and d) $t = 40$ ns. A well and a less crystallized clusters are displayed. Pt atoms are blue and Ni brown. Argon atoms are not displayed for clarity. Colors only online.

Figure 5 displays zoom of Pt₃Ni clusters at $t = 20$ and $t = 40$ ns and a cross section of typical Pt₃Ni clusters. They are identical to the Pt₃Ni core of Pt₃NiAu. This means that the Au segregation towards cluster outer surface does not affect the Pt₃Ni core.

Concerning Pt₃NiAu cluster composition, it is worth to note that the individual cluster composition calculated from snapshot data of Figure 1, is close to the Pt₃NiAu nominal one (with a standard deviation within 10 % at $t = 20$ ns and within 6 % at $t = 40$ ns). All clusters

display systematically a Pt₃Ni crystalline core structure, similar to the one obtained without Au, with an Au sub-monolayer covering this core structure as shown in cross-sections of Figures 2c and 2d. This is consistent with the very lower surface energy of Au compared to those of Pt and Ni as determined experimentally [43], as well as from theoretically determined EAM interaction potentials (table 1). It was previously shown that Pt surface atoms remain accessible for Pt_xPd_yAu catalysts [18] with Au atomic ratio lower than 25 at%; this is also confirmed for Pt₃NiAu with Au atomic ratio of 20 at%, as Pt surface atoms can be observed on snapshots in Figures 2a and 2b.

3.2 Pt₃Cu (+Au) growth

MD simulations were also carried out for the growth of Pt₃CuAu and Pt₃Cu under the same conditions as for Pt₃NiAu. Figure 6 provides a zoom at 40 ns on Pt₃CuAu typical clusters. At this stage, there is peanut-like and spherical-like nanoparticles. As in the case of Pt₃NiAu nanoparticles, the formation of a core PtCu alloy is predicted, as well as the segregation of Au to the surface of nanoparticles (no PtAu alloy formation). But, the main important information is that MD simulations predict the formation of AuCu alloys on the surface of the Pt₃CuAu nanoparticles, which is not the case with Pt₃NiAu material. Moreover, contrary to Pt₃NiAu, Pt₃CuAu are well crystallized. Cuboctahedron are present as well as structures corresponding to two partially coalesced cuboctahedrons leading to peanut like shapes. Snapshots at 20 ns and 40 ns as well as corresponding size distributions for Pt₃CuAu and Pt₃Cu are presented in Figures S2 and S3 of supporting information, respectively.

Figure 6: Typical Pt₃CuAu nanoparticles at t=40 ns. a) Surface structure, b) cross-section. Pt atoms are blue, Cu tan, and Au pink. Argon atoms are not displayed for clarity. Colors only online.

Figure 7 provides the corresponding zoom of Pt₃Cu at 40 ns. The Pt₃Cu nanoparticle structures are identical to the structure of the Pt₃Cu core of Pt₃CuAu core. Moreover, Cu segregation towards the Pt surface is clearly visible. This makes surface Au alloying with Cu likely to occur.

Figure 7: Typical Pt_3Cu nanoparticles at $t=40$ ns. a) Surface structure, b) cross-section. Pt atoms are blue and Cu tan. Argon atoms are not displayed for clarity. Colors only online.

The differences observed in the structures of Pt_3NiCu and Pt_3CuAu , Pt_3Ni and Pt_3Cu , are due to the different surface energies (table 1). The surface energy for Cu is lower than that for Ni and not so far from that for Au. So surface alloying of AuCu is expected, while Cu segregation to Pt surface is likely to occur, but to less extend than for Au. Moreover, EAM potentials include electronic interactions which also play a role in the clustering process. It is thus interesting to note here that Ni and Cu behave differently in the growth process of multi-metallic nanoparticles.

Table 1: Experimental [43] and EAM deduced surface energies [34] in Jm^{-2} .

	Pt	Ni	Cu	Au
EAM (111) face	1.44	1.45	1.17	0.79
EAM (100) face	1.650	1.58	1.28	0.92
EAM (110) face	1.750	1.73	1.40	0.98
Experimental (average face)	2.49	2.38	1.79	1.50

4. Discussion

Mattei et al. [44] used gas-phase technique such as gas aggregation source (also called low energy cluster beam deposition) for the synthesis of Au-Pt-Pd ternary systems (to provide active sites for enhanced catalytic activity) and investigated the parameters that govern the nucleation and growth of each element into monometallic clusters and alloy nanoparticles by means of classical MD simulations. In agreement with theoretical calculations, they observed that the element having the lower energy very often tends to segregate at the surface even without post annealing. The trends were then a segregation of Pt atoms to the core of NPs whereas Au atoms tended to segregate to the surface and to create a single-layer envelope surrounding the particles. These experimental and theoretical results are in full agreement with those presented in this article for Pt_3NiAu and Pt_3CuAu nanomaterials.

The phase diagrams of the Ni-Pt and Cu-Pt systems clearly indicate that the formations of defined Pt_3Ni and Pt_3Cu alloy phases are possible at low temperatures [45, 46], and the syntheses of $\text{Pt}_x\text{Ni}_{10-x}$ and $\text{Pt}_x\text{Cu}_{10-x}$ alloys were already performed by wet chemistry at room temperature [21, 47- 49]. Then, the formations of the PtNi and PtCu alloys predicted by MD simulations are consistent with experimental results.

The second important prediction of MD simulation concerns the formation of $\text{Au}_y\text{Cu}_{1-y}$ alloy at the surface of the nanoparticles, whereas AuNi alloys are not formed. This prediction agrees with studies on AuCu and AuNi phase diagrams showing that the Cu-Au system forms ordered compounds whereas Ni-Au system forms phase-separate compounds [50]. Indeed, for atomic ratio of 1:1, as it is the case in the present study, the formation of AuCu alloy can occur in a temperature range from ca. 0 °C to ca. 400 °C [51]. For AuNi, the formation of a FCC alloy phase occurs only at very high temperatures, i.e. higher than 900 K; at lower temperature, separate Ni-rich FCC and Au-rich FCC structures coexist [50,52].

The third important prediction from the MD simulations is that gold atoms are segregating towards the surface of the nanoparticles forming a sub-monolayer. This result agrees with the fact that Pt and Au are not or very slightly miscible at low temperatures. Indeed, according to the Pt-Au phase diagram proposed by Okamoto and Massalski [53], for an atomic ratio of 20 % in gold as in the case studied in this paper, the minimum temperature for the formation of a Pt-Au alloy is higher than 900 K. Although the synthesis of materials at the nanoscopic level may help to decrease the alloying temperature, it is expected that Pt and Au phase segregation occurs at the temperature considered in the present work (300 K), in agreement with MDs simulations.

At first glance, the formation of metastable state, as homogeneous Pt-Au nano-alloys or Pt@Au nanoparticles, are generally difficult to achieve, or even impossible, by conventional synthesis techniques. Pt-Au nano-alloys are generally synthesized by complex chemical methods involving at the end of the synthesis processes high temperature treatments [54, 55], whereas the formation of NPs where Au is placed in the NPs core can be obtained by using GAS when Au is sputtered with Ag or Co in specific conditions [56].

However, a simple wet chemistry synthesis method allows producing Pt-Au alloys over a large Pt/Au atomic ratio range, without any thermal treatment. Indeed, the “water in oil” microemulsion method has been used for this purpose [22, 57], although no theoretical information was given to explain this unexpected result. Yet, Lankiang et al. [22] have shown that these Pt-Au alloys (and Pt₃NiAu) underwent gold enrichment of their surfaces under electrochemical stress (potential cycles between 0.6 V and 1.05 V [21] or 1.25 V vs. RHE [22]). This enrichment was shown to be responsible of the decrease of the activity towards ORR, gold being much less active than platinum for this reaction. Because the electrode potential is directly related to the energy exchange ($\Delta G + nF\Delta E = 0$), the phase segregation (segregation of gold atoms from the bulk of nanoparticles towards their surface) translates into a low stability of the alloyed PtAu nanoparticles which tends towards the formation of a core shell structure, in agreement with previous theoretical studies based on molecular dynamics simulations [58], Monte-Carlo simulations [59] and density functional studies [19, 60]. These results also confirm those of our MDs simulations showing that Au atoms preferentially segregate at the ternary Pt₃NiAu nanoparticles.

In the case of Pt₃CuAu material, the nanoparticle surface did not undergo gold enrichment, and it was shown that these catalysts were more stable upon potential cycling than Pt₃NiAu [21]. This can be explained by the formation of an AuCu alloy close to the nanoparticle surface, as predicted by the MD simulations in the present work, as well as by DFT calculations by Jennings et al. [61]. These last authors concluded indeed that core atoms such as Cu having preferential bonding to Au will improve the stability of the nanoparticle.

5. Conclusion

Molecular dynamics simulations have been carried out for describing the growth process of free (unsupported) Pt₃NiAu and Pt₃CuAu nanocatalysts. Starting from an initial random metal vapor immersed in a buffer argon gas, the cluster growth is evolving with systematic core shell structure, with Au being segregated at the surface of the nanoparticles. At all steps of the simulations, Pt₃Ni and Pt_xCu ($x < 3$) bulk alloys are formed, consistently with Pt₃Ni and Pt₃Cu growth in identical conditions. An important difference between both systems is the formation of an AuCu alloy at the surface of the Pt₃CuAu nanoparticles, whereas in the case of Pt₃NiAu the formation of an AuNi alloy is not predicted. The vapor/cluster temperature evolution is revealing the different steps, nucleation, aggregation and coalescence of the nanocatalyst growth. The growth, composition and structure are consistent with previous finding on low temperature synthesis methods by wet chemistry and gas-phase technique such as gas aggregation source. Although the “water in oil” microemulsion method allowed synthesizing PtAu alloys, accelerated aging tests under potential cycling of Pt₃NiAu led to segregation of gold at the nanoparticle surface pointing out the low stability of PtAu alloys. In contrary, in the case of Pt₃CuAu catalyst, accelerated aging tests didn’t led to gold surface enrichment of the particles and the stability of the catalyst was enhanced. This is likely related to the formation of the AuCu alloy at the surface of nanoparticles that stabilizes them and avoid the gold segregation to the surface. The convergence between MDs, DFT and experimental results gives a consistent picture for linking electrochemical behavior with structure and composition of Pt₃NiAu and Pt₃CuAu nanocatalysts.
