Abstract

This paper presents the first autoregressive with exogenous input (ARX) model using energy expenditure, carbohydrates on board, and insulin on board as input to predict interstitial glucose (IG). The proposed model may be used for predicting IG even during physical activity (PA). A population-based model, obtained from a first database composed of 14 type 1 diabetes (T1D) patients, achieved a root-mean-square error (RMSE) of 16.7 ± 15.6 mg/dL, on IG prediction (30-min ahead) at the end of a PA, on a second database (15 T1D patients). Patient-specific ARX models, obtained on the second database, improved prediction accuracy ($\text{RMSE} = 7.8 \pm 4.5$ mg/dL), outperforming the results found in the literature.

Keywords: Interstitial glucose prediction, Physical activity, Energy expenditure, Meal, Insulin, T1D.

1. Introduction

Type 1 Diabetes (T1D) is a disease, where the insulin-producing cells (beta cells) are destroyed by the autoimmune system, causing a failure on blood glucose (BG) control. **BG > 300 mg/dL may lead to fatigue, nausea, abdominal pain, excessive thirst, frequent urination and blurred vision.**

June 14, 2019

Chronic hyperglycemia ($BG > 180$ mg/dL) may lead to long-term complications affecting eyes, kidneys, nerves and particularly the cardiovascular system. $BG < 70$ mg/dL (hypoglycemia) may lead to seizures, coma, and death. In fact, glucose is absorbed into the bloodstream after digestion of carbohydrates (CHO) in a meal, i.e., meals provoke an increase in BG. Glucose is also produced by the liver. Insulin is a hormone that allows glucose in the bloodstream to enter into cells, providing them with the energy they need to function, i.e., insulin provokes a decrease in BG. In this sense, the challenge for patients with T1D is to correctly dose their insulin administration in order to maintain their BG level into a target range, typically $BG \in [70, 180]$ mg/dL.

Interstitial glucose (IG) prediction plays an important role for automatically maintaining BG level of T1D patients into the targeted range. For instance, suspending insulin delivery when predicted IG is lower than a given threshold, allows reduction in hypoglycemic events [1, 2]. As an other example, Model Predictive Control (MPC) algorithms use predicted IG to optimize insulin delivery [3, 4]. In fact, a recently CE marked artificial pancreas (CE marking is a symbol of free marketability in the European Economic Area), uses IG predictions for regulating BG. For more details on this promising technology see [5] and [6]. The reader shall notice, that in this paper we make the difference between IG and BG. IG, which is provided by a continuous glucose monitoring (CGM) system and is highly correlated to BG [7], is the measure used by the artificial pancreas to regulate BG.

There exists a wide variety of models for predicting IG from a variety of input variables. In [8], three different model types: autoregressive (AR) models, AR models with exogenous input (ARX) and models based on an artificial neural network (ANN), were proposed. The AR-based models proposed in [8] only use IG information to perform IG prediction, whereas ARX and ANN-based models proposed in [8] use IG and insulin information. In [9], the predictive models receive as input variables IG, meal and insulin data. The models consist of a state-space model, an ARX model and an ARMAX model (autoregressive moving average with exogenous input). In [10, 11], two continuous-time second-order transfer functions are used with one using IG and injected insulin as inputs and the other using IG and amount of CHO of a meal. In [12], a hybrid model combining physiological (insulin and meal sub-models) and black box models (glucose-insulin interaction model and interstitial-continuous glucose monitoring model), was proposed. In [13] and [14] autoregressive integrated moving-average (ARIMAX) models are used

into an MPC algorithm. The two ARIMAX models use IG and injected insulin as inputs to predict IG. Prediction horizon in [13] was 100 min. In [14] prediction horizon was set to 10 hours. In [15], a state-space model, receiving insulin and IG as inputs, is used to predict IG in a horizon of 45 min. Prediction is used by an MPC algorithm to optimize insulin delivery.

Previous works are very interesting, **but in their IG prediction models, no physical activity (PA) information (level, type, or sensor data) was considered as input variable.** However, it is well-known that PA has a considerable effect on BG [16]. Authors in [17] demonstrated that the effect of PA on BG depends on the type (aerobic or resistance) and the intensity of the exercise. While aerobic physical activities induce a decrease on BG, resistance exercises induce an increase. Authors in [18] use a PA tracking watch to identify the “net” effect of idle, mild, moderate and intensive PA on BG. The aim of these studies was not to physiologically model the effect of PA into BG due to the complexity of this task. In fact, PA provokes an increase of blood flow in heart, lungs and peripheral tissue and a decrease of flow of kidneys and splanchnic organs [19, 20]. Peripheral glucose, insulin uptake, and liver’s glucose production are increased during PA [20]. Glycogen depletion and replenishment are also affected by the intensity of PA [20]. Moreover, it is well known that insulin sensitivity is also affected during and after PA [21, 22]. Two physiological models considering most of these effects were proposed in [20] and [23]. In [20] PA level is measured as a volume percentage of the maximum oxygen consumption (VO_2^{MAX}). Depending on the VO_2^{MAX} , redistribution of blood flow, periphery glucose uptake, hepatic glucose production, and periphery insulin uptake are modulated in their model. In [23], PA level is measured indirectly using the heart rate (HR). Depending on the HR, insulin-independent glucose clearance, insulin sensitivity (up to 22 hours), and glucose uptake are modulated in their model. Although these physiological models are very interesting, validation on real patients was never performed. The reader shall notice that, it is very difficult to quantify the effect of PA on the physiological variables affecting the BG behaviour. In fact, this effect depends on a large variety of factors such as body weight, age, sex, physiological condition, patient training level, PA type and intensity [16], [21].

System identification is an alternative solution already used for considering the effect of PA in IG prediction. For instance, in [24], a subspace-based patient-specific model is proposed for IG prediction on T1D patients during 30 min of exercise. The model receives CHO, insulin, HR, and respiration

rate as inputs. In their model, PA is estimated by using HR, however, it is well known that HR is also modulated by stress [25]. This fact may affect IG prediction accuracy in some situations. In [26], Dasanayake *et al.* proposed, a state-space model, which only receives IG and accelerometer signals as inputs. However, their model is only accurate, on IG prediction during PA, when heart rate is higher than 30% of the heart rate reserve (HR^r). In [27], an hybrid model uses as inputs the meal and insulin information, and rate of perceived exertion (to consider PA). Since PA is considered through the patient perception, model performance may be affected. In [28], a model using insulin on board, energy expenditure (computed from accelerometer and HR signals) and galvanic skin response as inputs was proposed. The model, consisting of an ARMAX model, does not receive meal information as input. Therefore, IG prediction accuracy after meals may decrease.

In this paper, we propose an ARX model that uses energy expenditure (EE), insulin on board (IOB), and carbohydrates on board (COB), as inputs for predicting IG. EE, computed from both accelerometers and HR signals [29], is used to better consider the effect of PA on IG prediction, as demonstrated in [28] and [30]. IOB is computed from the output of an insulin pump. COB is computed from the CHO declared by the patients. Differently to the ARMAX model used in [28], the ARX model proposed in our paper includes the COB as input. This fact, allows to consider the effect of CHO, usually ingested before and during PA to prevent hypoglycemia, in order to improve prediction. **Another difference between the ARMAX model presented in [28] and our ARX model is the intended use. While the ARMAX model proposed in [28] was designed to be used in an artificial pancreas that does not require meal announcement, the ARX model proposed in our paper is designed to be used in a hybrid closed-loop artificial pancreas. We could discuss the advantages and disadvantages of both approaches (meal announcement vs unannounced meal), but this is not the aim of this paper. The aim of this paper is to improve IG prediction during and after physical activities.**

In this sense, originality of the proposed ARX model is the fact of using EE, IOB, and COB as inputs variables. We consider that the use of these three variables, usually modulated during (EE, IOB, COB) and after (IOB, COB) a PA, may improve IG predictions.

The rest of the paper is organized as follows: Section 2 presents a detailed description of the experimental protocols to acquire the two databases used in this paper. Section 3 describes the proposed ARX model, and the validation tests. Results, presented in Section 4, are discussed in Section 5. Finally,

145 Section 6 presents the conclusions of the study.

146 2. Database description

147 Two different databases were used in this paper to estimate and validate
148 the proposed ARX model. The first database was acquired from a clinical
149 protocol where patients performed a single PA, namely “SPA protocol”. The
150 second database was acquired from a clinical protocol where patients per-
151 formed four PAs, namely, “FPA protocol”. These protocols were approved
152 by the “French Ethics Committee” and the “French National Agency for
153 Medicines and Health Products Safety (ANSM)”.

154 2.1. SPA database description

155 T1D patients ($N = 35$, age > 18 years old, $HbA1c < 10\%$) already treated
156 by insulin pump, were included in the clinical protocol, which was performed
157 on 7 centers in France, in 2012.

158 After two visits, inclusion analysis and installation/calibration of two con-
159 tinuous glucose monitoring systems (Dexcom[®] SEVEN[®] PLUS), patients
160 were hospitalized during 25 hours. Fig. 1 illustrates the SPA experimental
161 procedure.

162 Patients arrived at 18:30 in the afternoon. An intravenous catheter, an
163 insulin pump (JewelPUMP[™]), an accelerometer (hip-worn GT3X+, Acti-
164 Graph), and a PA monitoring system (Actiheart, CamNtech) were placed.
165 Meals were taken at fixed hours (20:00, 8:00 and 12:00). Patients performed
166 a PA at 15:00 during 30 min. The required PA, which consists of a step test,
167 was performed at moderate intensity according to each patient. From the
168 35 initial patients, fourteen patients wearing the accelerometer and the HR
169 monitoring system were included on this study. According to the proposed
170 PA protocol, patients reduced basal insulin rate during the half hour of PA
171 + 2 hours. Moreover, when patient risked hypoglycemia (based on current
172 and previous CGM measures), snacks were ingested and declared by patient.

173 Fig. 2 shows, for one patient of the SPA database, data set acquired
174 during the second day of visit 3 of this experimentation. We can observe
175 that 1) HR and counts per minutes (CPM), increase during PA (PA started
176 at 15:00), 2) for this patient, HR and CPM also increase between 10:00
177 and 11:00, which indicates that this patient performed an undeclared PA,
178 3) meal have an important and delayed effect on IG (IG increases around
179 40 min after meal), 4) as already mentioned, insulin basal rate is reduced

Figure 1: SPA study procedure was performed on visit 3. Subjects arrived at 18:30 and took dinner at 20:00 of day 1 of visit 3. On day 2 of visit 3, patients took breakfast and meal at 8:00 and 12:00, respectively, and performed a PA at 15:00 during 30 min.

180 when the patient started the PA in order to prevent hypoglycemia. More
 181 precisely, the aim of Fig. 2 is to illustrate data set used in this work to
 182 estimate (order selection and parameter estimation) the ARX model, i.e.,
 183 data set $\in [t_{PA} - 360, t_{PA} + 120]$ min, where t_{PA} is the time at which PA was
 184 started. This time interval was used on all the patients of the SPA database.

185 2.2. FPA database description

186 T1D patients (N=36, age > 18 years old, $7.5\% < \text{HbA1c} < 9.5\%$),
 187 already treated by insulin pump, and able to practice at least one PA during
 188 3 days, were included in the clinical protocol, which was performed in 9
 189 centers in France, in 2016.

190 This study was performed in 3 visits (see Fig. 3). During the first visit,
 191 inclusion was performed, CGM system (DexcomTM Share AP, Dexcom Inc.,
 192 San Diego, CA) was installed and calibrated, patients were instructed on the
 193 CGM system utilization, patients were randomized on 2 groups, and dates
 194 for visits 2 and 3 were established.

195 Visit 2 was done two days before the main visit (V3). An accelerometer
 196 (hip-worn GT3X+, ActiGraph), and a PA monitoring system (Actiheart,
 197 CamNtech) were placed.

Figure 2: Data set (of a SPA database patient) used in this work for modeling (from 5:00 in the morning to 17:00 in the afternoon). Breakfast, and meal were taken at 8:00, and 12:00, respectively. Patients performed a PA at 15:00 during 30 min.

Figure 3: FPA study procedure was performed on 3 visits. During the main visit patients arrived at 8:00 and stayed in the research center during 3 days, and performed 4 physical activities (PA1, PA2, PA3, and PA4).

Concerning the visit 3 (see Fig. 3), patients arrived to the research center at 8:00 (after taking breakfast at home), and spent 72 hours in the research center. If patients were in group A, they used a closed-loop Diabeloop artificial pancreas, i.e., the CGM DexcomTM Share AP, the smartphone Samsung (integrating the Diabeloop AP algorithm), and the insulin pump Cellnovo. If patients were in group B, they used open loop, i.e., the CGM DexcomTM Share AP and, their own insulin pump and usual treatment. Acquisition systems were started at 10:00.

During visit 3, patients performed daily physical activities, but also some imposed physical activities. Meals, of various CHO quantities, were taken at the same hours during the three days. Imposed physical activities were performed at fixed hours. Intensity and duration of physical activities were not the same during the three days of the visit. When PA started 3h after meal, each patient reduced the insulin basal rate at 50 or 80 % of the current basal rate, depending on the PA intensity, 30 to 60 min before starting the PA. When PA started within the 3h after meal, bolus correcting meal was reduced. When required (hypoglycemia risk), snacks were ingested and declared by the patient. From the 36 initial patients, fifteen patients wearing the accelerometer and the heart rate monitoring system were included on this study.

Fig. 4 displays, for one patient of the FPA database, data set acquired during the 3 days of visit 3. We can observe that patients performed a PA during day 1 (PA1), a PA during day 2 (PA2), and two PAs during day 3 (PA3 and PA4). We can also observe that when patient risked hypoglycemia, snacks were ingested (see small increases in CHO, in the third CHO panel).

In both protocols (SPA and FPA), CGM calibration was performed 1) at the installation phase by two BG measurements, 2) when instructed by the 12-hour CGM calibration prompt, and 3) when the CGM reading was inaccurate. In SPA protocol and the main visit of FPA protocol, BG was measured, by a glucose meter, at least every hour, but also every 15 min during meals, PA, hypoglycemia, and hyperglycemia.

In both protocols (SPA and FPA), IG was acquired every 5 min, declared PA, declared CHO, insulin basal rate, bolus, and HR (computed from electrocardiogram) were sampled every min. Accelerometer signals were converted in counts per minute. Finally all the signals were preprocessed and re-sampled to a sampling period of 10 min, which is the sampling period used in the proposed ARX model.

The 14 patients of the SPA protocol and the 15 patients of the FPA protocol, used in this study (good quality of CGM, CPM, and HR signals), were different. In fact, SPA and FPA protocols were performed on different years (2012 and 2016).

In both studies (SPA and FPA), CHO and PA type, were declared by the patients.

3. The proposed ARX model

This section presents the ARX model proposed in this paper. Differently to the black box models found in the literature (for instances [28, 30, 26, 24]), the proposed ARX model uses EE, IOB, and COB as inputs to improve IG prediction. These inputs allow to consider 1) the intensity and duration of a PA, 2) the delivered insulin which is modulated (before and during PA) to reduce the risk of hypoglycemia, and 3) the CHO, usually ingested before and during PA to prevent hypoglycemia. Notice that these are important factors affecting BG dynamic.

Figure 4: Data set (of a FPA database patient) used in this work for modeling (estimation and/or validation). Initialization was performed at 10:00. Breakfast, meal and dinner were taken at 8:00, 12:00, and 19:00, respectively. Patients performed a PA at 17:00 during 30 min or 45 min. Patients also performed a PA at 12:00 of day 3.

250 3.1. ARX structure

251 In system identification, ARX models are among the most used black box
252 structures due to their simplicity [31, 32]. The ARX model is given by (1).

$$y[k] = \mathbf{a}^T \mathbf{y}_{k-1} + \mathbf{b}^T \mathbf{u}_{k-nk} + e[k] \quad (1)$$

253 where k is the current sample. Both $\mathbf{a} = [a_1, \dots, a_{na}]$ and $\mathbf{b} = [b_1, \dots, b_{nb}]$
254 are the model parameters. The regressors $\mathbf{y}_{k-1} = [y[k-1], \dots, y[k-na]]$
255 are the previous outputs on which the current output ($y[k]$) depends. The
256 regressors $\mathbf{u}_{k-nk} = [u[k-nk], \dots, u[k-nk-nb+1]]$ are the delayed inputs
257 on which the current output depends. The parameters na and nb are the
258 orders of the ARX model, nk is the time delay (expressed in samples) before
259 the input affects the output, also called the dead time of the system. Finally,
260 $e[k]$ is a noisy value.

261 3.2. Proposed ARX model structure

262 ARX models may be used for representing multiple-input and single-
263 output (MISO) systems. In this paper, the proposed ARX model, given
264 by (2), receives as inputs the IOB computed according to (3), the COB
265 computed according to (4), and the EE computed according to (6). The
266 black box model in (2) will determine the temporal relations that may exist
267 between the inputs IOB, COB, EE and the output IG. Model parameters
268 are estimated from MISO data in order to dynamically represent the effect
269 of inputs into IG.

$$\hat{y}^{\text{IG}}[k] = \mathbf{a}^T \mathbf{y}_{k-1}^{\text{IG}} + \mathbf{b}^T \mathbf{u}_{k-nk_1}^{\text{EE}} + \mathbf{c}^T \mathbf{u}_{k-nk_2}^{\text{IOB}} + \mathbf{d}^T \mathbf{u}_{k-nk_3}^{\text{COB}} \quad (2)$$

270 The ARX model, proposed in this paper, used a sampling period of 10 min,
271 according to previous works found in the literature [9, 28]. However, predic-
272 tions may be performed every 5 min (sampling period of IG), i.e., every 5
273 min the ARX model resamples the past signals to 10 min in order to predict
274 IG [10, 20, 30, $\dots$, N] min ahead. In this paper we present examples of 30,
275 60 and 120 min ahead IG predictions.

276 3.3. Model inputs

277 3.3.1. IOB input

278 The IOB refers to the injected insulin (bolus and basal), that is still to
279 have an effect on the BG. The IOB is computed as a convolution:

$$u^{\text{IOB}}[n] = \sum_{k=0}^K I[n-k] h_{\text{IOB}}[k] \quad (3)$$

where $I[k]$ is the quantity of insulin in mU delivered by the insulin pump at the k -th time index.

3.3.2. COB input

In the same spirit, the COB refers to the portion of the meal that is still to have an effect on the IG. The COB is computed as a similar convolution:

$$u^{\text{COB}}[n] = \sum_{k=0}^K \text{CHO}[n-k] h_{\text{COB}}[k] \quad (4)$$

where $\text{CHO}[k]$ is the quantity of CHO in g ingested at the k -th time index. As already mentioned, CHO were declared by the patients.

In (3) and (4), $K = 144$ to consider 24h of data, and $h[k] = h[k\tau_s]$ with $\tau_s = 10$ min, is given by (5):

$$h[k] = \left[1 + \frac{k}{\tau} \right] e^{-\frac{k}{\tau}}. \quad (5)$$

$\tau = 50$ min in (3) was set from a population-based study (SPA protocol), where insulinemia was measured every 10 min during a given period. $\tau = 40$ min in (4) was empirically set. We considered the fact that CHO have usually a faster effect on IG than insulin.

3.3.3. EE input

The EE is computed from accelerometer and HR signals, according to (6).

$$u^{\text{EE}} = \begin{cases} \alpha_1 \text{HR}^r + \beta_1, & \text{if } \text{HR}^r \geq S_{\text{HR}^r}, \\ \alpha_2 \text{LC} + \beta_2, & \text{if } \text{HR}^r < S_{\text{HR}^r} \text{ and } \text{LC} < S_{\text{LC}}, \\ \alpha_3 \text{LC} + \beta_3, & \text{if } \text{HR}^r < S_{\text{HR}^r} \text{ and } \text{LC} \geq S_{\text{LC}}. \end{cases} \quad (6)$$

where $\alpha_1 = 5.45$, $\beta_1 = -66.09$, $\alpha_2 = 256.09$, $\beta_2 = -0.13$, $\alpha_3 = 85.99$, $\beta_3 = 82.39$ are the model parameters. $S_{\text{HR}^r} = 40$ bpm and $S_{\text{LC}} = 0.5$ are the cut points obtained from a population-based approach. LC is a linear combination of the normalized values of HR^r and CPM, computed as:

$$\text{LC} = \theta_1 \text{CPM} + \theta_2 \text{HR}^r.$$

where $\text{HR}^r = \text{HR} - \text{resting HR}$, CPM are the counts per minute (a quantity derived from the accelerometer signal [33]).

Notice that, in this model, PA information declared by the patients is not used to compute EE. For more details on model (6) see [29].

3.4. Model orders and delays

The orders (na , nb , nc , and nd) and delays (nk_1 , nk_2 , and nk_3) of the ARX model proposed in this paper, were obtained by a standard system identification methodology, described in the following.

- 1) na , nb , nc , nd , nk_1 , nk_2 , and nk_3 are changed among a given range of values,
- 2) each time that na , nb , nc , nd , nk_1 , nk_2 , or nk_3 changes, model parameters are estimated, by the classical least squares algorithm (7), and an associated Akaike final prediction error (FPE) is computed by (8).

$$\hat{\theta} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}, \quad (7)$$

where $\mathbf{X}$ is the regression matrix, $\mathbf{y}$ is a $N \times 1$ vector of outputs (IG in this case), and $\hat{\theta}$ represents the estimated parameters.

$$FPE = \frac{1 + d/N}{1 - d/N} \left(\frac{1}{N} \mathbf{e}(k, \hat{\theta}) (\mathbf{e}(k, \hat{\theta}))^T \right), \quad (8)$$

where N is the number of values in the estimation data set, $\mathbf{e}(t, \hat{\theta})$ is a vector of prediction errors, and d is the number of estimated parameters ($\hat{\theta}$).

- 3) the model structure (orders and delays) leading the lowest final prediction error is chosen as the best candidate. Notice that by using this selection criteria (8) the overparametrization is penalized.

Database used for choosing the model structure (orders and delays) was the SPA database. Datasets into the span $[t_{PA} - 360 \text{ min}, t_{PA} + 120 \text{ min}]$ sampled at $\tau = 10 \text{ min}$, were used for training.

Accordingly with the system identification procedure described above:

- 1) model orders and delays were changed in the ranges: $na \in [1, 10]$, $nb \in [7, 8]$, $nc \in [10, 15]$, $nd \in [10, 15]$, $nk_1 \in [1, 2]$, $nk_2 \in [1, 2]$, $nk_3 \in [1, 3]$;
- 2) each time that a given set of orders and delays was set: a) a regression matrix was constructed for each patient, b) the regression matrix of aull patients was concatenated, c) a model (parameters) was estimated, by the least squares algorithm, and d) a final prediction error associated with such model is computed;
- 3) finally, the model structure (orders and delays $na = 3$,

332 $nb = 5$, $nc = 11$, $nd = 7$, and $nk_1 = nk_2 = nk_3 = 2$), yielding the lowest final
 333 prediction error was chosen as the best candidate. It is interesting to notice
 334 that the selected model structure allows to consider the effect of IOB in the
 335 interval $[t - 130 \text{ min}, t - 20 \text{ min}]$, and the effect of COB in the interval $[t -$
 336 $90 \text{ min}, t - 20 \text{ min}]$. These time intervals cover the periods where insulin [34]
 337 and CHO [35] have the most important effect on BG.

338 3.5. ARX validation tests

339 The goals of the validation tests presented in this paper are 1) to evaluate
 340 the possibility of proposing a population-based ARX model, 2) to verify the
 341 hypothesis on ARX models stating that performance of personalized ARX
 342 models may increase as the number of quality-training-data increases, and
 343 3) to test the improvement achieved by using the three regressors.

344 3.5.1. Test 1: The population-based ARX model obtained from the SPA database 345 is evaluated on the FPA database

346 As a first approach, we evaluated the possibility of using an ARX model
 347 for predicting IG in any T1D adult patient. In this sense, ARX parameters
 348 (**a**, **b**, **c**, and **d** in (2)) are obtained from data sets on which model orders and
 349 delays were chosen. Similar to the model structure selection, the concate-
 350 nated regression matrix was used to obtain the SPA population-based ARX
 351 parameters. Then, the population-based (PB) model was used for predicting
 352 IG on the 15 patients of the FPA database, during 30, 60 and 120 min, after
 353 the physical activity (PA3) was started (see Fig. 4).

354 3.5.2. Test 2: Increasing ARX performance by increasing training data

355 We hypothesize, according to literature [36], that black box models per-
 356 formance may increase, if the number of quality-available-training data in-
 357 creases. In this sense, patient-specific ARX models were obtained on the
 358 FPA database from:

- 359 a) a single data set (T1), i.e., data around PA1, PA2, or PA4 is used
 360 separately for training;
- 361 b) on two data sets (T2), i.e., data around PA1 and PA2, PA1 and PA4,
 362 or PA2 and PA4 is used for training;
- 363 c) on three data sets (T3), i.e., data around PA1, PA2, and PA4 is used
 364 for training.

We refer to data around a given PA, as a set of 8 hours of data into the span $[t_{\text{PA}i} - 60, t_{\text{PA}i} + 360 \text{ min}]$, where $t_{\text{PA}i}$ is the time at which one of the physical activities PA1, PA2 or PA4 was started. In this sense models T1 are trained on 8 hours of data, T2 models are trained on 16 hours of data, and T3 models are trained on 24 hours of data.

Finally, T1, T2, and T3 ARX models were used for predicting IG, into the span $[t_{\text{PA}3}, t_{\text{PA}3} + 30 \text{ min}]$, $[t_{\text{PA}3}, t_{\text{PA}3} + 60 \text{ min}]$, and $[t_{\text{PA}3}, t_{\text{PA}3} + 120 \text{ min}]$.

3.5.3. Test 3: Improvement achieved by the use of the three variables (insulin, meal, and EE)

On the FPA database, we obtained 1) T3 models using COB, IOB, and EE as inputs, 2) T3 models using only COB and IOB as inputs (NEE), 3) T3 models using only EE and IOB as inputs (NCOB), and 4) T3 models using only EE and COB as inputs (NIOB). Models T3, NEE, NCOB, and NIOB, are compared in order to show the improvement reached by the use of three simultaneous variables as inputs of the ARX models.

3.6. Performance indicator

Performance indicator used for measuring model accuracy is the root-mean-square error (RMSE), given by:

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{n=1}^N (y^{\text{IG}}[n] - \hat{y}^{\text{IG}}[n])^2}, \quad (9)$$

which is a standard indicator used in IG prediction [8, 9, 10, 11, 12]. In (9), $y^{\text{IG}}[n]$ and $\hat{y}^{\text{IG}}[n]$, are the measured and predicted IG at instant n , respectively. Since in tests described above the ARX models are used for predicting IG during 30, 60, and 120 min, and the sampling period was 10 min, then $N = 3, 6$, and 12 , respectively.

P-value, computed by Wilcoxon Matched-Pairs signed-rank test [37], which is a non-parametric statistical hypothesis test, was used for validation on test 3, described above.

4. Results

Parameters of the proposed PB ARX model were $a1 = 1.67$, $a2 = -0.74$, $a3 = 0.06$, $b1 = -1.03$, $b2 = 1.87$, $b3 = -0.71$, $b4 = 1.35$, $b5 = -0.12$, $c1 = 3.39e^{-4}$, $c2 = -1.09e^{-4}$, $c3 = -0.34e^{-4}$, $c4 = -3.02e^{-4}$, $c5 = 3.82e^{-4}$,

Figure 5: Parameters of the personalized ARX models derived from T3 models. Since parameters were personalized for 15 patients, each box is composed of 15 points, i.e., each parameter can take 15 values. Parameters of the PB model are also displayed (blue points), representing the value of each parameter.

395 $c_6 = -3.73e^{-4}$, $c_7 = -1.19e^{-4}$, $c_8 = 2.63e^{-4}$, $c_9 = -1.26e^{-4}$, $c_{10} = 3.37e^{-4}$,
 396 $c_{11} = -1.74e^{-4}$, $d_1 = 0.57e^{-2}$, $d_2 = -0.73e^{-2}$, $d_3 = 0.45e^{-2}$, $d_4 = -0.08e^{-2}$,
 397 $d_5 = -0.59e^{-2}$, $d_6 = 0.98e^{-2}$, and $d_7 = -0.54e^{-2}$.

398 Fig. 5 displays the parameters of the 15 patient-specific ARX models
 399 (boxplots) obtained for T3 models. On the same figure, parameters of the
 400 population-based ARX model (PB-model) are also represented (single blue
 401 points).

402 We observe in Fig. 5 that all the parameters of the PB model are inside
 403 the boxplots, i.e., min and max values of each parameter of the T3 models.
 404 Moreover, the parameters a_3 , $\mathbf{b}$, $\mathbf{c}$, and $\mathbf{d}$ are inside the interquartile range,
 405 i.e., first and third quartiles. We see that the coefficients a_1 , a_2 are roughly
 406 opposite, which means that, as expected, the prediction is sensitive to the

Table 1: RMSE (mean $\pm$ standard deviation) computed for IG prediction during 30, 60 and 120 min, performed by models T3, T2, T1, and PB.

Model	30 min (mg/dL)	60 min (mg/dL)	120 min (mg/dL)
T3	7.75 ± 4.51	15.86 ± 9.61	35.24 ± 19.52
T2	8.94 ± 6.17	19.11 ± 12.24	41.22 ± 28.01
T1	21.82 ± 17.02	81.78 ± 120.61	327.04 ± 473.29
PB	16.70 ± 15.56	31.67 ± 25.84	44.50 ± 30.45

Table 2: P-values, by Wilcoxon Matched-Pairs signed-rank test, from comparisons between RMSE reached by the model T3 and the models NEE, NCOB, and NIOB, on IG prediction during 30, 60 and 120 min.

Model	30 min	60 min	120 min
NEE	0.03	0.04	0.28
NCOB	0.35	0.30	0.04
NIOB	0.52	0.21	0.08

current IG slope. Since the proposed ARX model is a black box model, more explanation on the meaning of the rest of parameters may not be given.

Fig. 6 (left) shows results of tests 1 and 2. Performance reached by the ARX models obtained from different training data sets are represented by boxplots T3, T2, and T1, respectively. Performance of the SPA population-based ARX model is represented by boxplot PB. Table 1 presents (mean $\pm$ standard deviation) RMSE on IG prediction during 30, 60 and 120 min, performed by each model.

Fig. 6 (right) displays results of test 3, i.e., RMSE reached by models T3, NEE, NCOB, and NIOB. Table 2 displays p-values (obtained by Wilcoxon Matched-Pairs signed-rank test) of the comparison between the T3 models and the NEE, NCOB, and NIOB models, on IG prediction during 30, 60, and 120 min.

Finally, Fig. 7 illustrates a representative example of 30 min ahead IG prediction, performed by the proposed T3 model (considering EE, IOB, and COB as inputs), on one patient of the FPA database. As already mentioned, even if the ARX model uses a sampling period of 10 min, IG prediction may be performed every 5min, as is the case in this example.

Figure 6: (left) Performance on IG prediction by ARX models trained on 1, 2, and 3 data sets, i.e., T1, T2, and T3, respectively. Model trained on the SPA population is also included (PB). Models are used for predicting IG during 30 min (top panel), 60 min (middle panel), and 120 min (bottom panel). (right) Performance on IG prediction by ARX models, trained on 3 data sets. Models T3 uses EE, COB and IOB as inputs. Models NEE uses COB and IOB. Models NCOB uses EE and IOB as inputs. Models NIOB uses EE and COB as inputs. The four models are used for predicting IG during 30 min (top panel), 60 min (middle panel), and 120 min (bottom panel).

Figure 7: IG prediction 30 min ahead, by a patient-specific ARX model using as inputs EE, COB, and IOB (i.e. a T3 model). Every 5 min, the ARX model uses re-sampled signals (10 min) to predict IG 30 min ahead.

5. Discussion

Fig. 5 shows that parameters of the population-based ARX model, obtained from the SPA database, are within the ranges of parameters of the patient-specific ARX models obtained from the FPA database. Therefore, performance reached by the PB model is good (compared with the obtained patient-specific models) for IG predictions (during 30, 60, and 120 min) on the FPA database. In fact, in [26], authors reported an average mean absolute error (MAE), over 15 patients, during 30 min of IG predictions (during PA) of 19.7 mg/dL. The PB model proposed in this paper reached an average MAE of 14.93 mg/dL, over 15 patients, during 30 min of IG prediction. Considering these results we can conclude that the proposed PB model is more accurate than the model presented in [26] on 30-min IG predictions. But the two models were not developed under the same conditions and for the same goal: 1) the model that we propose in this paper allows IG prediction during and out of PA periods, whereas the model proposed in [26] is only accurate on PA periods; 2) the model proposed in this paper uses EE (from HR and accelerometer signals), IOB, and COB (from CHO declared by the patient) as exogenous inputs, whereas the model proposed in [26] only uses accelerometer signals; 3) experiments in [26] were different of those performed in this paper. In fact, this is the first time that SPA and FPA

445 protocols are reported in a paper. For these reasons, a true comparison may
446 not be established.

447 Fig. 6 (left) allows us to demonstrate that performance of patient-specific
448 ARX models increases if the number of training data increases. We can
449 observe that, for T3 models trained on 24 hours of data, the RMSE on IG
450 prediction during 30, 60 and 120 min is lower than RMSE obtained by models
451 T2 and T1, i.e., models trained on 16 and 8 hours of data, respectively. Table
452 1 confirms these results quantitatively. Mean RMSE reached by T3 models is
453 three times lower than the one obtained by models T1 on IG prediction during
454 30 min, five times lower on IG prediction 60 min ahead and nine times lower
455 on IG predictions 120 min ahead. Comparing T3 and T2 models, difference
456 in performance is less important than that observed while comparing T3 and
457 T1 models, but T3 models remain more accurate.

458 Fig. 6 (right) shows that models using EE, COB and IOB as inputs are
459 more accurate than those models using only IOB and COB, on 30 and 60 min
460 ahead IG predictions. A p-value lower than 0.05 was found, when evaluating
461 the difference between T3 and NEE models. However, a p-value = 0.28 was
462 found on IG prediction during 120 min. These results may be interpreted as
463 follows. When a T1D patient performs a PA, the use of EE as input in the
464 models is very important (during PA and even 30 min after PA). However,
465 when the effect of the performed PA is reduced (120 min after PA), the
466 use of EE as input is less important, but, as showed in Fig. 6 (right), still
467 allows improvement in performance. Concerning the effect of suppressing
468 the COB input or the IOB input of the models, T3 models reached better
469 performance than NCOB and NIOB models on the three prediction horizons,
470 but difference was not significative.

471 Finally, Fig. 7 shows an example on 30 min ahead IG prediction, by the
472 T3 model during a day (day 3 of visit 3 of the FPA protocol shown in Fig.
473 3). We can observe that the proposed model is good for predicting IG during
474 PA but also out of PA. Therefore we consider that this model may be used
475 on any application where 30 min ahead IG prediction is required, regardless
476 of whether or not, the patients is performing a PA.

477 In fact, other works have reported results on 30 min ahead IG prediction
478 by linear black box models. In [8] an AR model, using only IG information
479 as input, reached a RMSE ranged between 14.0 and 21.6 mg/dL, whereas an
480 ARX model, using IG and insulin information as inputs, reached a RMSE
481 ranged between 13.3 and 18.8 mg/dL. These results are promising, however,
482 estimation and validation were done on a virtual population, and the model

483 was not confronted to the complex dynamics of IG on real T1D patients. In
 484 [9], a state-space model, receiving meal and insulin data as input variables,
 485 reached a RMSE = 18.08 mg/dL on IG prediction 30 min ahead, on a real
 486 T1D patient. In [12] a model combining physiological and black box models,
 487 reached RMSE of 19.1, 19.5, and 21.1 mg/dL on IG prediction during 20,
 488 40, and 60 min, respectively. The reader shall notice that similar to our
 489 model, in these works insulin and IG information is automatically acquired
 490 by an insulin pump and a CGM system, respectively. CHO information is
 491 manually reported by the patients. However, experiments performed in these
 492 works (PA is not considered) are different to those performed in our study.
 493 Therefore, a comparison between results reported by the other works and
 494 ours may not be fair. But, RMSE reached by our models, using EE, COB,
 495 and IOB as inputs, trained on 24 hours of data (i.e., T3 models), on IG
 496 prediction during 30 and 60 min (RMSE = 7.75 ± 4.51 and RMSE = 15.86
 497 ± 9.61 , respectively), on 15 T1D patients, show the interest of this paper.

498 5.1. Limitations

499 The main limitation of the study is that models were performed and
 500 validated on two databases composed of adult patients. Then, we can not
 501 assure that proposed models will accurately predict IG on children or ado-
 502 lescent patients. Other limitation of the proposed model is the inability to
 503 accommodate for disturbances that may occurs in the prediction horizon.
 504 In fact, predictions are based on past and current data, then future meals
 505 and physical activities will not be considered on the IG prediction. Other
 506 limitation is the fact of using IOB and COB time constants at fixed val-
 507 ues (one population-based and the other empirically chosen). In fact, these
 508 time constants, which are patient dependent variables, may affect IG predic-
 509 tion performed by the proposed models. Another, limitation of the proposed
 510 model is that insulin sensitivity, which is also a patient dependent variable
 511 that varies during the day, is not considered by the model. This limita-
 512 tion may be overcome by adapting the model parameters during the day
 513 [8]. Finally, a limitation concerns the heart rate and accelerometer sensors
 514 errors. For instance, in Fig. 4 (bottom panel) some sensors errors (HR < 50
 515 bpm) are displayed. Although sensors signals were processed on this work,
 516 online signal processing may not lead to the same results. This limitation
 517 will be overcome with the advance of sensor technologies (measurements and
 518 connectivity).

519 6. Conclusion

520 This paper presented ARX models for predicting IG during and after PA.
521 We showed that a population-based ARX model may be used for predicting
522 IG 30 min ahead with an acceptable accuracy. We demonstrated that per-
523 formance of the ARX models increases when the number of training data
524 increases. This result is very interesting, since on T1D patients using an
525 artificial pancreas, the number of quality training data will increase through
526 time. However, patients' physiology also evolves through time, then training
527 data should be correctly chosen. In fact, data collected a long time ago may
528 not be representative of the patient's BG dynamics. Finally, we showed the
529 interest of using meal, insulin, and physical activity information as inputs to
530 increases performance on IG prediction during and after PA. In fact, current
531 models found in the literature are limited to predicting IG during PA (insulin
532 or meal are not used as inputs), or out of a PA (EE is not used as input).
533 The fact of considering the 3 variables as inputs, allows the proposed model
534 to perform accurate IG predictions during and out of PA.
