Disentangling the evolution of a coherent mean-flow and turbulent fluctuations, interacting through the nonlinearity of the Navier-Stokes equations, is a central issue in fluid mechanics. It affects a wide range of flows, such as planetary atmospheres, plasmas, or wall-bounded flows, and hampers turbulence models. We consider the special case of a two-dimensional flow in a periodic box, for which the mean flow, a pair of box-size vortices called “condensate,” emerges from turbulence. As was recently shown, a perturbative closure describes correctly the condensate when turbulence is excited at small scales. In this context, we obtain explicit results for the statistics of turbulence, encoded in the Reynolds stress tensor. We demonstrate that the two components of the Reynolds stress, the momentum flux and the turbulent energy, are determined by different mechanisms. It was suggested previously that the momentum flux is fixed by a balance between forcing and mean-flow advection: using unprecedentedly long numerical simulations, we provide the first direct evidence supporting this prediction. By contrast, combining analytical computations with numerical simulations, we show that the turbulent energy is determined only by mean-flow advection and obtain for the first time a formula describing its profile in the vortex.

DOI: 10.1103/PhysRevLett.120.204505

More often than not, turbulence appears hand in hand with a coherent mean flow. At high Reynolds numbers, the interactions between the two are strong, and closed equations describing each component separately cannot be obtained. This is a central problem in fluid mechanics [1], with far-reaching consequences. Indeed, turbulence retroacts on the mean flow, through a term called the “Reynolds stress tensor,” which encapsulates the important physical quantities: the turbulent momentum flux and the turbulent energy. For instance, numerical models that do not fully resolve turbulence require a parametrization of the Reynolds stress [2]. This term also drives atmospheric jets such as the jet stream, which governs weather at mid-latitudes [3]. It is therefore crucial to better understand the statistics of this object.

While an understanding of the interactions between a mean flow and turbulence remains elusive for general 3D flows, progress can be made for the class of quasi-2D flows, such as planetary atmospheres, plasmas, or wall-bounded flows, and hampers turbulence models. We consider the special case of a two-dimensional flow in a periodic box, for which the mean flow, a pair of box-size vortices called “condensate,” emerges from turbulence. As was recently shown, a perturbative closure describes correctly the condensate when turbulence is excited at small scales. In this context, we obtain explicit results for the statistics of turbulence, encoded in the Reynolds stress tensor. We demonstrate that the two components of the Reynolds stress, the momentum flux and the turbulent energy, are determined by different mechanisms. It was suggested previously that the momentum flux is fixed by a balance between forcing and mean-flow advection: using unprecedentedly long numerical simulations, we provide the first direct evidence supporting this prediction. By contrast, combining analytical computations with numerical simulations, we show that the turbulent energy is determined only by mean-flow advection and obtain for the first time a formula describing its profile in the vortex.

condensate is expected to become asymptotically strong compared to turbulence when the large-scale dissipation rate tends to zero, which justifies a perturbative treatment. More precisely, if the mean-flow shear rate is much larger than the rate of nonlinear turbulence-turbulence interactions, then the latter can generically be neglected. This is called the quasilinear approach: it has inspired statistical closures for quasi-2D flows, such as stochastic structural stability theory [7] or, equivalently, cumulant expansion [8]. The idea has also been applied to 3D wall turbulence [9] and investigated numerically in atmospheric dynamics [10]. For a pronounced mean flow, this approach can be justified theoretically using adiabatic reduction [11], but has some success also outside that regime [12]. Actually, if turbulence is excited at asymptotically small scales, the perturbative treatment allows us to analytically derive an explicit formula for the mean-flow and momentum flux profiles, as demonstrated for the vortex condensate [13,14] and discussed for jets [15,16] and on the sphere [4]. Until now, the only part of these predictions that was quantitatively checked against data from direct numerical simulation (DNS) is the profile of the mean flow [13].

In this Letter, we present new results on the statistics of the Reynolds stress in 2D. First, using long time integration, we provide the first numerical evidence supporting the explicit formula for the momentum flux [13,14]. Second, we show that the turbulent energy is determined by a different mechanism: while the momentum flux results from a balance between forcing and shear at small scales,
the mean flow can be approximated locally by a hyperviscosity, and $F$ is a random forcing. We work with an isotropic, white in time forcing acting in a narrow shell in Fourier space centered on wave number $K_f$, with $v = \langle \mathbf{v} \cdot \mathbf{F} \rangle$ the average energy injection rate [17].

DNS results are obtained by integrating (1) using the GHOST pseudospectral code, at resolution $512^2$ and $1024^2$, with parameters $L = 2\pi$, $K_f = L/\ell_f = 100$, $p = 16$, and $\nu = 5 \times 10^{-35}$. We carried out runs covering almost 2 orders of magnitude in the friction coefficient $\alpha$ (see Table 1). In agreement with previous studies, the flow reaches a condensate steady state, taking the form of a vortex dipole (see Fig. 1). The vortices drift slowly across the box, with fast turbulent fluctuations superimposed on them. We carry out a Reynolds decomposition in polar coordinates centered on one of the vortices: the mean flow, no experimental or numerical evidence has been given for the average momentum flux (2). The difficulty is that it is a small quantity $[\langle uv \rangle / U^2 = O(\delta^{1/2})]$ and it is not sign definite: the average value results from cancellations of strongly fluctuating contributions.

As shown previously [13,14,16], within the quasilinear approximation—justified for $\delta \ll 1$—and once $K_f \gg 1$, so that the mean flow can be approximated locally by a uniform shear, it is possible to derive an explicit formula for the mean flow $U$ and momentum flux $\langle uv \rangle$

$$ U = \sqrt{3e/\alpha}, \quad \langle uv \rangle = -r \sqrt{a e/3}. $$

This profile is expected to hold in the range $\ell_f \ll r \ll R_u$, where $R_u = \delta^{-1/2} K_f^{-2/3} L$ measures the radius where the rate of nonlinear interactions is comparable to the mean-flow shear rate. At larger radii, the quasilinear approximation is expected to break, while for $r \ll \ell_f$, the uniform shear approximation for the mean flow is no longer applicable. Of course, once $R_u \gg L$, the range of validity should be set by the boundary—be it a wall or a second vortex. The mean-flow profile in our simulations (shown in the Supplemental Material [17]) is compatible with the theoretical prediction in a region that expands with decreasing $\delta$. This is consistent with earlier numerical results [13], over a wider range of friction coefficient $\alpha$. In the figures, we represent the range $\ell_f \ll r \ll R_u$ by a shaded area and the empirical range of validity by vertical dashed lines. Focusing on this region, we now discuss the three terms of the average Reynolds stress tensor: $\langle u^2 \rangle$, $\langle v^2 \rangle$, and $\langle uv \rangle$.

The average momentum flux profile.—Until now, unlike the mean flow, no experimental or numerical evidence has been given for the average momentum flux (2). The difficulty is that it is a small quantity $[\langle uv \rangle / U^2 = O(\delta^{1/2})]$ and it is not sign definite: the average value results from cancellations of strongly fluctuating contributions. Leveraging the hybrid parallelization of GHOST [22], we were able to integrate our runs over extremely long times (about 320 000 turnover times) and accumulate enough statistics to observe partial convergence of the average momentum flux $\langle uv \rangle$, shown in Fig. 2. Although convergence is restricted to a subregion of the region of interest that does not match the empirical range defined above, we find that the momentum flux is consistent with the prediction (2): the numerical data unambiguously confirm the negative sign and the scaling with $\alpha$ and are compatible.

TABLE I. Parameters for the DNS runs.
with the theoretical prediction at the outer edge of the region, \( r/L \lesssim 10^{-1} \) (smaller radii have less statistics).

The average turbulent energy profile.—Symmetry considerations imply that the magnitude of the diagonal terms of the Reynolds tensor, \( \langle u^2 \rangle \) and \( \langle v^2 \rangle \), as well as the mechanism that dictates them, are different than those for the momentum flux [13,14]. We therefore take a different approach than [23], where the turbulent energy is computed within the same framework used for the momentum flux. Instead, we will show that \( \langle u^2 \rangle \) and \( \langle v^2 \rangle \) are determined by the zero modes of the advection equation for two-point correlation functions. Indeed, in the quasilinear framework, fluctuations are linearly advected by the mean flow. Because of incompressibility, the dynamics is characterized by a single field: vorticity, for instance, obeys the equation

\[
\partial_t \omega + \Omega \times \omega = f_\omega, \quad \partial_t \Phi + \nabla \times \Phi = \omega, \quad \text{with} \quad \Phi = \langle \omega_1 \omega_2 \rangle,
\]

where \( f_\omega = \langle f_{\omega_1} f_{\omega_2} \rangle \), the steady-state advection equation reads

\[
[H^{(1)} + H^{(2)} + \Delta_1 + \Delta_2] \Phi = 2C.
\]

The mean-flow profile (2), however, holds only in part of the domain. Furthermore, we are eventually interested in velocity statistics. Therefore, we transform this equation into a partial differential equation for the radial velocity correlation function, using incompressibility: \( \partial_v \partial_\phi \Phi = \Delta_1 \Delta_2 r_1 r_2 \langle v_1 v_2 \rangle \). We now claim that \( \langle v_1 v_2 \rangle \) is dominated by zero modes of the resulting advection operator. This entails two approximations. First, we neglect the contribution from dissipation. This is justifiable in the region \( r_1, r_2 \ll R_a \), where fluctuations are weak compared to the mean flow. Second, we neglect the injection by the forcing, which is justified as long as \( |r_1 - r_2| \gg \ell_f \). In fact, we eventually need to take the limit \( r_1 \to r_2 \), passing through \( \ell_f \), to compute the energy \( \langle u^2 \rangle \) and \( \langle v^2 \rangle \). However, for \( K_f \gg 1 \), we expect to recover the correct result in this limit, since velocity correlation functions should be continuous—the energy being mainly determined at scales larger than the forcing scale. We shall solve explicitly the resulting homogeneous advection equation characterizing the zero modes, with the mean-flow profile (2). It reads

\[
|\ell_2 r_2 (2\partial_\ell_1 r_1 + L_1) - \ell_1 r_1 (2\partial_\ell_1 r_2 + L_2)] \partial_\phi \langle v_1 v_2 \rangle = 0,
\]

with the notation \( L_i = r_i^2 \Delta_i \), using isotropy (\( \partial_\phi \Phi = -\partial_\theta \Phi \)).

Given the form of the advection operator, it is natural to decompose the fluctuations into angular harmonics: 

\[
v(r, \phi) = \sum_{m=-\infty}^{\infty} \hat{v}_m(r) e^{im\phi} \quad \text{(and similar for } u)\]

The resulting equation for \( \langle \hat{v}_m(r_1) \hat{v}_m(r_2) \rangle \) is scale invariant and independent of the value of the mean flow \( U \). This prompts the ansatz 

\[
\langle \hat{v}_m(r_1) \hat{v}_m(r_2) \rangle = r_f^2 f_m(r_2/r_1),
\]

which allows us to convert our partial differential equation into an ordinary differential equation in the variable \( R = r_1/r_2 \).

It can be written compactly as the hypergeometric equation [24]:

\[
4 \sum_{i=1}^{\infty} \left( \frac{R}{dR} - y_i \right) f_m(R) = R \prod_{i=1}^{4} \left( \frac{R}{dR} + \alpha_i \right) f_m(R),
\]

with the parameters \( \langle y_1, y_2, y_3, y_4 \rangle = \left( \lambda - m, \lambda + m, -1 - \sqrt{m^2 - 1}, -1 - \sqrt{m^2 - 1} \right) \), \( \alpha_1, \alpha_2, \alpha_3, \alpha_4 = (1 - m, 1 + m, -\lambda + \sqrt{m^2 - 1}, -\lambda - \sqrt{m^2 - 1}) \), and \( \lambda = \lambda + 1 \). This equation has four families of solutions, described in detail in the Supplemental Material [17], each parametrized by \( m \) and \( \lambda \).

We now turn to the numerical simulations to identify which solutions derived in our theoretical framework (i.e., which parameters \( \lambda \)) contribute to the turbulent energy profile.

Decomposing the DNS data into harmonics, we see that turbulent energy in the region of interest is strongly dominated (about 90%) by the \( m = 1 \) modes (see the dashed curve in Figs. 3 and 4 and also the Supplemental Material [17]). Figure 3 also suggests that, in the universal region, \( \langle \hat{u}_1 \hat{u}_2 \rangle \approx \hat{\delta} \langle \hat{v}_1 \hat{v}_2 \rangle \approx \text{const} \), and \( \langle \hat{v}_1 \hat{v}_2 \rangle \approx \text{const} + r^\beta \) with some \( \beta < 0 \). Comparing this form to the possible solutions to (4), we find that it corresponds to a unique superposition of two solutions, one with \( \lambda = 0 \), which has 

\[
\langle |\hat{v}_1|\rangle \approx \langle |\hat{v}_1|\rangle \approx \text{const, and } \langle |\hat{v}_1^2| \rangle \approx \text{const + r}^\beta
\]

Indeed, a very good match to such a power law can be seen in Fig. 4, once \( \langle |\hat{v}_1|\rangle \) is subtracted from \( \langle |\hat{v}_1^2| \rangle \). In its current form, our theory does not determine the scaling of the correlation functions with \( \delta \). We again turn to the DNS results and find that \( \langle \hat{u}_1^2 \rangle \) and \( \hat{\delta} \langle \hat{v}_1 \hat{v}_2^\dagger \rangle \) collapse for the different runs when rescaled by \( \delta^{1/3} \), while the \( r^2 \) part of \( \langle |\hat{v}_1|\rangle \) scales like \( \delta^{-1} \). However, we also have \( U^2 \propto \delta^{-1} \).

![FIG. 2. Rescaled profile of average momentum flux \( \langle uv \rangle \) from DNS. The horizontal blue line corresponds to the theoretical prediction. Vertical dashed lines denote the range where the mean-flow profile (2) is observed to hold.](image-url)
FIG. 3. Profile of the first harmonic $|\langle \hat{u}_1 \rangle|^2$ for all the runs, rescaled according to (5). The dashed purple line corresponds to the same quantity, normalized by the full field $\langle u^2 \rangle/2$ for run E. (Inset) The ratio $\langle \hat{u}_1 \hat{v}_1 \rangle / \langle |\hat{u}_1|^2 \rangle$ and we have relied throughout on the ratio $|\langle \hat{v}_1 \rangle|^2 / U^2$ being small. Thus, we expect this term to be suppressed by some power of $K_f^{-1}$. We finally obtain

$$
\langle |\hat{v}_1|^2 \rangle = (\epsilon R_u)^{2/3} \left[ A_1 + A_2 \left( \frac{R_u}{L} \right)^{4/3} \left( \frac{\ell_f}{r} \right)^2 \right].
$$

FIG. 4. Rescaled profile of the power law part for the first harmonic $|\langle \hat{u}_1 \rangle|^2 - |\langle \hat{u}_1 \rangle|^2$, for all the runs. The dashed purple line corresponds to the same quantity, normalized by $\langle v^2 - u^2 \rangle/2$ for run E.

The agreement with these formulas observed in Figs. 3 and 4 improves with decreasing $\delta$. The constant part of the $m = 1$ mode is probably due to uniform shifts of the vortex, induced by turbulent fluctuations. A detailed study of such mechanisms is left for future work.

The mode $m = 1$, which dominates the energy, is the lowest mode determined by mean-flow advection. Indeed, as a consequence of the isotropy of the mean flow, it does not interact with the $m = 0$ harmonic. Note also that the zeroth harmonic of the radial velocity $v$ identically vanishes due to incompressibility. Formulas for higher-order harmonics, however, can be deduced from our formalism. Let us demonstrate that with $m = 2$. The DNS results indicate that $\langle \hat{u}_2 \hat{v}_2 \rangle$ is constant in the universal region. In addition, since $\lambda = -2$ contributes to $m = 1$, we check if it contributes to $m = 2$ as well. This leads to a superposition of three solutions: the first has $\lambda = 0$ and is of the form $f^{(1)}_2(R) = R^{\sqrt{3} - 1} g(R)$, for $R \leq 1$, where $g(R)$ is a quadratic polynomial. The two other solutions have $\lambda = -2$, and they come in a particular combination, which reads $f^{(2)}_2(R) = R^{\sqrt{3} - 1} - (\sqrt{3}/2)R$ for $R < 1$ [17]. Like for $m = 1$, we use the DNS data to identify the scaling with $\delta$ and deduce the coefficients in the combination of solutions. This gives

$$
\langle |\hat{v}_2|^2 \rangle = (\epsilon \ell_f)^{2/3} \left[ B_1 - B_2 \left( \frac{R_u}{L} \right)^{4/3} \left( \frac{\ell_f}{r} \right)^2 \right],
$$

$$
\langle |\hat{u}_2|^2 \rangle = (\epsilon \ell_f)^{2/3} \left[ \frac{19}{28} B_1 - \frac{\sqrt{3}}{2} B_2 \left( \frac{R_u}{L} \right)^{4/3} \left( \frac{\ell_f}{r} \right)^2 \right],
$$

$$
\langle \hat{u}_2 \hat{v}_2 \rangle = i \frac{B_1}{2} (\epsilon \ell_f)^{2/3}.
$$

Figure 5 shows that DNS data seems compatible with (6), except close to the inner boundary of the region, which
could either come from the contribution of another solution or a forcing effect.

We finally note that an analog of (3) was used in a previous attempt [25] to determine the momentum flux and mean flow. There, the hierarchy was closed at the level of cubic terms. As was later realized [13,14], this produces a zero momentum flux at any order, because the equations are invariant under the transformation $\phi \to -\phi$, $t \to -t$, while the momentum flux breaks this symmetry. The same happens with the zero modes discussed here: because the coefficients in (4) are real, are the solutions $\langle h_m(r_1) h^*_m(r_2) \rangle$, resulting in $\delta t ([\hat{u}_m \hat{v}_m^*]) = 0$.

Conclusion.—In this Letter, we have explored the turbulent fluctuations statistics in a 2D vortex mean flow sustained by turbulence. We demonstrated that the turbulent energy and momentum flux are governed by different mechanisms, dictated by symmetry. Through a combination of DNS and first-principles theoretical analysis, we showed, for the first time, that the turbulent energy profile (5)—and, more generally, two-point correlation functions—is determined by zero modes of the mean-flow advection equation. The contribution of these zero modes to the momentum flux vanishes, which explains why it is determined at next order by a balance between forcing and advection. We provided the first evidence supporting the resulting profile. A consequence is that the turbulent energy and momentum flux scale differently with the small parameter $\delta$, at variance with the assumption used to justify the quasilinear approach in a kinetic theory framework [11]. Moreover, while the limit $K_f \gg 1$ was discussed before [15], our results point to its crucial role in suppressing the fluctuations, which was not considered. We have relied upon DNS results to identify which theoretical solutions are realized and their scaling with $\delta$. This leaves open the question of their selection mechanism. In particular, it would be interesting to check if, in a box with solid boundaries, such as found in experiments, the turbulent energy profile would be the same or if, instead, other solutions would be selected. Our results also represent an important first step for understanding turbulence statistics in more complex flows, such as geophysical jets, plasmas, and ultimately, long-standing problems such as turbulent boundary layers.

The authors would like to thank two anonymous referees for useful comments which helped improve the manuscript. We are grateful to G. Falkovich for the many discussions we had at the initial stages of this work. Computer time was provided by the Weizmann Institute of Science on the Weizmann Exascale Cluster (WEXAC). C. H. would like to thank V. Golodnitsky for technical assistance with the cluster. A.F. is supported by a Princeton Center for Theoretical Science Fellowship.
