Keywords: Atmospheric deposit, Saharan dust, cation-nutrient recycling, Sr and Nd isotopes, Critical Zone.

Abstract:

The important fertilizing role of atmospheric dust, and particularly African dust, in tropical rainforests is increasingly recognized but still poorly quantified. To better evaluate dust input into the Caribbean basin, we sampled critical zone compartments of a small forested volcanic catchment in Guadeloupe (soils, parent rock, atmospheric dust, plants, soil solutions, stream and rain waters). The aims of this

22 study are to track sources of cation nutrients (Ca, Mg, K, Sr) developed on highly weathered soil in the
23 rainforest of Guadeloupe, to quantify plant recycling of these nutrients, and to identify constraints on
24 regolith development and its associated nutrient pool.

25 In the Quiock Creek catchment, a large isotopic range of $^{87}\text{Sr}/^{86}\text{Sr}$ and ϵNd values was observed despite
26 the small scale of observation. Sr isotopic composition of the dissolved load varied from 0.7084 in
27 rainfall to 0.7110 in soil solution, whereas it ranges between 0.7068 and 0.7153 for soil samples and
28 between 0.7096 and 0.7102 for plants. The Nd isotopic composition varied between -8.39 in near-
29 surface soil samples to 2.71 in deeper soil. All samples had an intermediate signature between that of
30 the bedrock endmember ($^{87}\text{Sr}/^{86}\text{Sr}=0.7038$; $\epsilon\text{Nd}=4.8$) and the atmospheric endmember (sea salt:
31 $^{87}\text{Sr}/^{86}\text{Sr}=0.7092$ and Saharan dust: $^{87}\text{Sr}/^{86}\text{Sr}=0.7187$, $\epsilon\text{Nd}=-11.5$).

32 The regolith was built on pyroclastic deposits, but, because of extreme leaching, the regolith has lost
33 its original bedrock signature and inherited an exogenous atmospheric signature. Our results show that
34 only the chemical weathering of the fresh near-surface minerals can provide nutrients to the ecosystem
35 (first 30 cm). However, this dust weathering is too low to sustain the tropical forest ecosystem on its
36 own. The cationic mass balance at the catchment scale, as well as the Sr isotopic signature, show that
37 cation and Sr fluxes are of atmospheric origin only and that original bedrock no longer participates in
38 nutrient cycles. The vegetation reflects the $^{87}\text{Sr}/^{86}\text{Sr}$ of the dissolved pool of atmospheric Sr.

39 At the soil-plant scale, the cation-nutrient fluxes provided by vegetation (litter fall + leaf excretion) are
40 major compared to input and output fluxes. The annual Ca, K, Sr and Mg fluxes within the vegetation
41 are, respectively, 31, 28, 20 and 3 times greater than the exported fluxes at the outlet of the basin. The
42 residence time of nutrients in the vegetation is 16 years for K and close to 45 years for Sr, Ca and Mg.
43 These results emphasize the highly efficient vegetative turnover that dominates the nutrient cycle in
44 the Quiock Creek catchment.

45 This first characterization of biogeochemical cycles in the Guadeloupean rainforest suggests that the
46 forest community of Quiock Creek is sustained by a small near-surface nutrient pool disconnected from

47 the deep volcanic bedrock. We also demonstrated that, even with efficient nutrient recycling, Saharan
48 dust plays a significant role in maintaining ecosystem productivity in Guadeloupe over long-time scales.

50 The base cations calcium, potassium and magnesium, are nutrient elements essential for plant
51 development as they are building blocks of tissues and chlorophyll and have a number of metabolic
52 functions. They also play a major role in neutralizing soil acidity and maintaining biological activity. In
53 ecosystems, base cations in soils and plants originate from in situ mineral weathering (*e.g.* Schlesinger,
54 1997). However, numerous studies have shown that, under specific circumstances, these elements can
55 be provided by the atmosphere through precipitation or dust (*e.g.* Dahms, 1993; Hedin et al., 1994;
56 Kennedy et al., 1998). Forest ecosystems are generally poor in nutrients and many studies have
57 suggested that atmospheric deposits are significant sources of nutrients (*e.g.* Hedin and Likens, 1996;
58 Okin et al., 2004; Soderberg and Compton, 2007; Pett-Ridge, 2009; Yu et al., 2015; Schuessler et al.,
59 2018). Nutrient depletion in soils is particularly high in tropical areas, where temperature and
60 precipitation combine to intensively leach nutrients from rocks and soil. In such contexts, the soil is
61 usually strongly impacted by atmospheric inputs (*e.g.* Whipkey et al., 2000; Kurtz et al., 2001; Poszna
62 et al., 2002; Pett-Ridge et al., 2009b). Cation nutrients, essential for plants, are thus expected to be
63 strongly influenced by atmospheric inputs in highly weathered soils. Several studies conducted in
64 Hawaii (Kennedy et al., 1998; Chadwick et al., 1999; Stewart et al., 2001), along chrono- and climato-
65 sequence gradients, have shown that the more soils are leached, the more associated plants are
66 influenced by atmospheric inputs. Other studies conducted in tropical areas of Costa-Rica (Bern et al.,
67 2005; Porder et al., 2006) have shown that the soil-nutrient pool could still be influenced by bedrock
68 weathering. The authors have suggested that rock-derived input was maintained by high erosion rates
69 or deep plant roots.

70 The transport of African dust into the Caribbean basin is relatively well documented, either by
71 measuring contemporary fluxes (*e.g.* Prospero et al., 1981; Prospero 1999) or by studying Quaternary
72 age geological limestone records found on the western Atlantic islands of Barbados, the Florida Keys,
73 and the Bahamas (*e.g.* Muhs et al., 1990; 2007). However, the number of soil record studies examining
74 the impact of Saharan dust inputs on nutrient cycling over pedogenic timescales of hundreds to

75 thousands of years is limited. Studies conducted in the Luquillo Mountains in Puerto Rico (Pett-Ridge
76 et al., 2009a; McClintock et al., 2015) have revealed that Saharan dust contributes significantly to
77 nutrient inputs into weathered soils. Recent studies (Dessert et al., 2015; Clergue et al., 2015; Fries et
78 al., 2019) have also tended to show that the soils of Guadeloupe can be strongly impacted by
79 atmospheric deposits. These few studies did not take into account internal nutrient cycles in the
80 watershed (e.g. litterfall, leaf excretion) and did not focus on the influence of dust on plants. However,
81 the characterization of these cycles is important from the perspective of ecological theory and the
82 understanding of Earth's Critical Zone.

83 As it is impossible to directly measure the cation-nutrient flux between rock, soil and vegetation, base
84 cation cycles in forested ecosystems are not straightforward to characterize. Sr and its radiogenic
85 isotopes have been shown to be proxies for cation-nutrient cycling in the atmosphere-soil-plant system
86 (e.g. Capo et al., 1998; Bern et al., 2005; Belanger et al., 2012; Stille et al., 2012). As calcium has a
87 hydrate ionic radius and an ionic charge similar to those of Sr, its behaviour can be deduced from the
88 $^{87}\text{Sr}/^{86}\text{Sr}$ ratio. K and Mg chemistry differs from that of Ca and Sr, but these lithophile elements
89 ultimately originate from the same sources. Their behaviour can be inferred from Sr isotope data
90 combined with on site element flux calculations. The efficient use of Sr isotopes as a cation-nutrient
91 cycle proxy necessitates that different Sr sources exhibit different $^{87}\text{Sr}/^{86}\text{Sr}$ ratios.

92 In Guadeloupe, possible common sources of Sr and base cation nutrients (volcanic rock, sea salt and
93 Saharan dust) differ in Sr isotopic signature. The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of volcanic bedrock is between 0.70341
94 and 0.70382 (White and Patchett, 1984; White and Dupré, 1986). The signature of sea salt is 0.70917
95 (e.g. Dia et al., 1992) and the $^{87}\text{Sr}/^{86}\text{Sr}$ mean ratio of Saharan dust is 0.71788 (Biscaye et al., 1974;
96 Grousset et al., 1988; Grousset et al., 1992; Rognon et al., 1996; Grousset et al., 1998; Pett-Ridge et al.,
97 2009). We looked at Sr isotopes, Nd isotopes, and base cation nutrients to identify their sources. Like
98 Sr, Nd isotope ratios are used to trace Nd sources, as they are not affected by biological and weathering
99 processes (e.g. Liu et al., 2013). The Nd signature in volcanic rock from Guadeloupe ranges from 3.02
100 to 5.05 (White and Patchett, 1984; White and Dupré, 1986) and the signature of Saharan dust varies

between -10.5 and -14.5 (Grousset et al., 1992; Dia et al., 2006). Nd and Sr differ in their mobility (Nd is less mobile than Sr) and are distributed differently in surface compartments, thus the comparison between these two isotopic systems provides complementary information on constraints in the study area.

In this study we report Sr isotope ratios in all compartments of a small catchment (rainfall, throughfall, soil solution, bulk soil, unweathered rock, river water, litter and atmospheric dusts) and Nd isotope ratios of soils and unweathered rock. The catchment is located in the tropical rainforest of Guadeloupe, in the Caribbean (FWI). This area is covered by highly weathered soils built on mono-lithological volcanoclastic deposits. Despite the poverty of the soils (Buss et al., 2010; Clergue et al., 2015), a dense rainforest is developed on it (Rousteau et al., 1994, 1996). The aims of this study are to: 1) Track sources of cation nutrients (Ca, Mg, K) of the rainforest of Guadeloupe developed on a highly weathered soil; 2) Quantify the vegetation recycling of cation nutrients; 3) Identify the origin of “rock-derived” cation-nutrient pool in the soil and give constraints on regolith development.

2. Site description

The studied catchment (16°17'N, 61°70'W) is located on Basse-Terre Island, the volcanic part of the Guadeloupe archipelago in the French West Indies (Fig. 1). The Quiock Creek drains a watershed of 8 ha, ranging from 200 m to 350 m in altitude, located in the primary tropical rainforest of the Guadeloupe National Park. The Quiock Creek catchment is monitored by the ObsErA observatory (OZCAR research infrastructure; Gaillardet et al., 2018) dedicated to the study of weathering and erosion processes under tropical climatic conditions (Clergue et al., 2015; Lloret et al., 2016; Fries et al., 2019; Guérin et al., 2019).

The climate on site is characterized by high mean annual temperature (25°C) and precipitation (3500 mm yr^{-1}). The mean annual runoff is 1,130 mm. Evapotranspiration is high, between 60 and 70% (Clergue et al., 2015; Guérin et al., 2019) and tropical storms and hurricanes contribute significantly to the hydrology of the site (Zahibo et al., 2007).

127 Quiock Creek is covered by a very thick ferralitic soil (>15 m thick; Colmet-Daage and Bernard, 1979,
128 IRD soil map) built on Pleistocene andesitic pyroclastic deposits (Boudon et al., 1988). The regolith
129 profile of Quiock Creek mainly consists of secondary minerals, with kaolinite/halloysite as the main
130 mineral (95% by weight of the bulk soil; Buss et al., 2010) and is highly depleted in mobile elements
131 (Buss et al., 2010; Clergue et al., 2015). All these features are characteristic of a highly weathered soil.
132 Despite the high nutrient depletion of these soils, they support a tropical rainforest (Rousteau et al.,
133 1996; Van Laere et al., 2016). This rainforest is characterized by three dominant species: *Amanoa*
134 *caribaea* Kr. and Urb. (Phyllanthaceae), *Tapura latifolia* Benth (Dichapetalaceae) and *Dracryodes excelsa*
135 *Vahl* (Burseraceae). The litter flux produced by this oldgrowth rainforest was determined each two
136 weeks using 10 litter traps of one square meter size each monitored for two years (2011–2013). Annual
137 litter flux reached 7.8 t.ha⁻¹.yr⁻¹ of dry matter (Rousteau, 2014), comparable to the rainforest flux in
138 northeastern Puerto Rico (Weaver and Murphy, 1990). The litter production is seasonal, with the
139 highest litter fall occurring in June-August (40% of the annual litter fall). Finally, the biomass measured
140 on site is equal to 376.8 t.ha⁻¹ (Rousteau, 2014).

141 Atmospheric inputs to the watershed come in two forms: wet deposits and dry deposits. Wet deposits
142 consist of rainfall, while dry deposits include sea salt aerosols, Saharan dust and volcanic ash. Because
143 of the location of the study site in the heart of the National Park, anthropic contributions are negligible.

144 One of the peculiarities of the Caribbean is the major input of Saharan dust (SD) up to 100 kg.ha⁻¹.yr⁻¹
145 measured in Guadeloupe (J. Molinié, personal communication) which is consistent with amounts
146 reported in the literature for the Caribbean basin (Glaccum and Prospero, 1980; Mahowald et al., 2006;
147 Pett-Ridge et al., 2009; Yu et al., 2015). Throughout the Caribbean region, Saharan dust is deposited on
148 the ground or on the canopy by rain. These dust deposits are mainly composed of mica/illite and quartz
149 (Prospero et al., 1970; Glaccum and Prospero, 1980). For instance, in the Quiock Creek soil profile, the
150 dull aspect of quartz, characteristic of aerial transport, suggests that Saharan dust is likely the source
151 of quartz.

Another exogenous input to the top soil comes from the neighbouring volcano Soufriere Hills on Montserrat, located 86 km NW of Guadeloupe. It erupted on July 18, 1995, after a century of quiescence. Since 1995, six recognized ash fall episodes have impacted Guadeloupe (www.mvo.ms; activity report of OVSG 2000). The two most important events took place in September 1996 and February 2010 and produced ash-fall deposits on Guadeloupe that were thicker than 1 mm, corresponding to fluxes of about 50 to 100 g m⁻² of ash each (Cadelis et al., 2013; OVSG reports). The volcanic ashes were mainly composed of crystalline silica, mostly cristobalite (Baxter et al., 1999).

All these atmospheric sources (sea salt and dust) have been shown to highly impact soil in the Caribbean Basin (e.g. Borg and Banner, 1996; Herwitz et al., 1996; Muhs et al., 2009; Pett-Ridge et al., 2009; Opfergelt et al., 2012; Clergue et al., 2015; Dessert et al., 2015; Fries et al., 2019).

3. Sample collection

All compartments of the watershed were sampled between 2011 and 2013. Water samples consisted of rainfall, throughfall, soil solution and river water, and solid samples consisted of soil, rock, litter and dust.

3.1. Water samples

We collected water samples during contrasting hydrological periods. River samples (QC, n=39) were collected manually once a month and more frequently during six field trips. Rainfall (RF, n=9), and throughfall (TF, n=48) were sampled during six field trips between 2011 and 2013. They both were collected in polypropylene bottles with a funnel located one meter above the ground in order to avoid contamination from soil particles. Rainfall were collected on site on the roof of the “Maison de la Forêt” (RF-MF) or at the “Observatoire Volcanologique et Sismologique de Guadeloupe” (RF-OVSG). These samples correspond to several rainfall events cumulated over 1 to 5 days, depending on the sample. Throughfall waters were collected by three collectors randomly positioned in the Quiock Creek catchment (collector n°1 to n°3) and were sampled every 1 to 5 days, depending on the sample. Soil

solutions (SS) were sampled using nested tension lysimeters equipped with porous ceramic cups located between 15 and 823 cm in depth (Buss et al., 2010). These soil solutions were sampled each month and the sampling dates selected for isotopic measurement were 10-26-2012 and 06-28-2013. Conductivity and pH were measured on site for the Quiock Creek samples and after collection at the OVSG for the other samples. For alkalinity measurements, non-filtered 20 mL aliquots were used. The remaining water was filtered through 0.2 μm cellulose filters and divided into two subsamples. One non-acidified aliquot was stored in polypropylene bottles and used for anion and silica analyses. The second aliquot was acidified (2% HNO_3), stored in polypropylene bottles and used for cation, trace element and Sr isotope measurements. Strontium isotopic compositions were measured on 26 selected samples corresponding to 3 samples of rainfall, 6 samples of throughfall, 4 samples of stream water and 13 samples of soil solution.

3.2. Solid samples

We analyzed andesite (04-GW-12) and basalt (00-GU-44 and 03-GU-75) samples from Samper et al. (2007) to characterize the unweathered parent rock (Fig. 1). A soil profile (n=27) was collected with a hand-auger down to 12.5 m depth during lysimeter installation in 2007 (Buss et al., 2010). We collected Saharan dust during a dust event deposit on July 1 and 5, 2013. It corresponds to rainfall particulate matter obtained by filtration on a 0.2 μm cellulose filter. The filter was then dried and stored in a Petri dish. We also analysed 5 samples of litter, collected during one of the most productive periods (between June 10 and 24, 2011). “Leaves 1” corresponds to a mixture of litter from different species (collected in the same litter collector) whereas “Leaves 2” corresponds to *Amanoa caribaea* leaves only. “Branches 1” and “Branches 2” correspond to a mixture of branches collected in two different litter collectors. Finally, “Roots” (April 2012) are from *Amanoa caribaea*.

4. Analytical methods and flux calculation

4.1. Solid sample digestion

202 Soil and litter samples were first dried in an oven (60°C) for 3 days and crushed in an agate mortar (soil
203 samples) or in a ball mill (litter samples). Soil and rock samples (100 mg) were dissolved in a mixture of
204 HNO₃/HF for 2 days at 120 °C. This mixture was then evaporated and dissolved twice in 2mL 6N HCl
205 and finally stored in 1N HCl. Saharan dust samples collected on cellulose filters underwent an initial
206 step of filter digestion in diluted 5N HNO₃ at 100°C for 1 day and were treated with the same protocol
207 as for rock and soil samples. Litter samples (500 mg) were first dissolved in 10 mL of 16N HNO₃ in 50
208 mL Teflon beakers for 24h at room temperature and then digested in a DigiPREP block digestion system
209 for another 24h at 90°C. After an evaporation step at 60°C, the samples were dissolved once more in
210 16N HNO₃ for 24h at 90°C. Finally, after evaporation, 0.5 mL HF/ H₃BO₃ were added to fully dissolve the
211 phytoliths. These samples were then stored in 50 mL of 2N HNO₃.

212 4.2. Major and trace element analyses

213 We measured base cations by ICP AES (ThermoFisher iCap 6200 series) at the Institut de Physique du
214 Globe de Paris (IPGP). Anions in soil solutions were measured with a Dionex DX 120 chromatograph at
215 the IPGP and the OVSG/IPGP. We quantified Sr concentrations using HR-ICP-MS (Element II
216 ThermoScientific) at IPGP. The limit of quantification is 20 ppt and repeated measurement of the SLRS-
217 5 standard lead to an external reproducibility of 3%.

218 Major elements in solid samples were measured by ICP AES (ThermoFisher iCap 6200 series) at the
219 IPGP. Trace elements in solid samples were measured with an ICP-MS X series mass spectrometer
220 (Thermo Electron) at the Institut des Sciences de la Terre de Paris (ISTeP) of the Université Pierre et
221 Marie Curie. We followed the bracketing method using BEN rock standards for bracketing and BEN,
222 GSN and LKSD2 to validate the measurements. The standard values measured in this study are
223 compared to the certified values to validate the data (Table S1). We measured major element and Sr
224 concentrations in litter samples using a calibration curve, such as for water samples. The accuracy of
225 this measurement was checked by repeated analyses of a vegetation standard NIST SRM 1515.

226 4.3. Sr and Nd purification

227 Sr and Nd isotope analyses were performed on the Neptune multicollector ICP-MS (Thermo Scientific)
228 at IPGP using the Apex sample inlet system. A prior step of purification is needed in order to avoid a
229 matrix effect during measurement.

230 The separation of Sr from the rest of the matrix was automated for water samples with HPIC (High
231 Performance Ion Chromatography) as fully described in Meynadier et al. (2006). Sr contained in
232 solubilized solid samples was separated from the rest of the matrix on Sr-Spec resin in 3N HNO₃ media.
233 The elution step was performed with milliQ H₂O. The resin was replaced after each separation to avoid
234 memory effects. The purified solution of Sr was evaporated and dissolved in 0.05N HNO₃ for isotopic
235 measurement. The minimum amount required for Sr isotopic measurement is 50-100 ng Sr in 1 mL.
236 For Nd separation, a two-step procedure was applied (Richard et al., 1976; Caro et al., 2006). First, rare
237 earth elements were separated from the rest of the matrix on TRU-Spec resin in 2N HNO₃ media. Then,
238 the separation of the different rare earth elements was performed on Ln-spec resin in 0.25N HCl media.
239 The purified Nd solution was evaporated and dissolved in 3N HNO₃ for isotopic measurement. The
240 minimum amount required for Nd isotopic measurement is 50 ng Nd in 1 mL.

241 4.4. Sr and Nd isotope analyses

242 For Sr, the method used corresponds to the measurement of 100 ratios of 4 second iteration time per
243 sample or standard. Mass interferences with Kr (84 and 86) were corrected using ⁸³Kr/⁸⁴Kr and ⁸³Kr/⁸⁶Kr,
244 measured in the blank at the beginning of each session. Mass interference with Rb (87) was corrected
245 using the ⁸⁵Rb/⁸⁷Rb ratio measured in a low concentrated Rb solution (2.5 ppb) after Kr measurement.
246 The mass bias was corrected using the ⁸⁶Sr/⁸⁸Sr ratio of 0.1194. Each measurement was normalized to
247 the NBS value certified as ⁸⁷Sr/⁸⁶Sr = 0.71025, which was measured every 3 samples. The standard error
248 based on repeated measurement of the NBS standard was 2% = 0.00001.

249 The εNd was calculated relative to the CHUR (Chondritic Uniform Reservoir) as follows:

$$250 \quad \epsilon Nd = \left(\frac{{}^{143}\text{Nd}/{}^{144}\text{Nd}_{\text{sample}}}{{}^{143}\text{Nd}/{}^{144}\text{Nd}_{\text{CHUR}}} - 1 \right) \times 10000 \quad (1)$$

251 The CHUR value is 0.512638 (Jacobsen and Wasserburg, 1980). The method used corresponds to the
 252 measurement of 100 ratios of 4 second iteration time per sample or standard. Mass interferences with
 253 Sm (144, 148 and 150) were corrected using $^{147}\text{Sm}/^{144}\text{Sm} = 4.83870$. The mass bias was corrected using
 254 the $^{146}\text{Nd}/^{144}\text{Nd}$ ratio of 0.72190. Each measurement was normalized to the NIST value certified as
 255 $^{143}\text{Nd}/^{144}\text{Nd} = 0.511418 \pm 6 \cdot 10^{-6}$ (Caro et al., 2006), which was measured every 3 samples. The external
 256 error was 0.18ϵ (2σ).

257 4.5. Cation flux and residence time calculation

258 Elemental fluxes were obtained by multiplying the water/matter flux by the mean concentrations or
 259 determined from the following equations. Water fluxes were determined in Clergue et al. (2015).
 260 Throughfall water flux is 3079 mm yr^{-1} . The Quioc Creek discharge ranges between 150 and 400 L min^{-1}
 261 with a mean value of 172 L min^{-1} , corresponding to a runoff of 1130 mm yr^{-1} . Dry matter litter flux
 262 reaches $7.8 \text{ t ha}^{-1} \text{ yr}^{-1}$ (Rousteau 2014).

263 Throughfall elementary fluxes (F_{TF}) are described by equation 2, where F_{EX} is the flux of cations exuded
 264 by plants, and F_{RF} the rainfall flux.

$$265 \quad F_{\text{TF}} = F_{\text{EX}} + F_{\text{RF}} \quad (2)$$

266 The rainfall compartment is influenced by both sea salt aerosols (F_{SW}) and Saharan dust leaching (F_{SD})
 267 and F_{RF} is equal to:

$$268 \quad F_{\text{RF}} = F_{\text{SW}} - F_{\text{SD}} \quad (3)$$

269 We consider that the flux of Cl in throughfall ($F\text{-Cl}_{\text{TF}}$) is exclusively from rainfall. F_{RF} is determined from
 270 the $F\text{-Cl}_{\text{TF}}$ and (X/Cl) rainfall ratios:

$$271 \quad F_{\text{RF}} = F\text{-Cl}_{\text{TF}} \times (\text{X/Cl})_{\text{RF}} \quad (4)$$

272 with $\text{Na/Cl}_{\text{RF}} = 0.63$, $\text{Ca/Cl}_{\text{RF}} = 0.09$, $\text{Mg/Cl}_{\text{RF}} = 0.09$, $\text{K/Cl}_{\text{RF}} = 0.05$; $1000\text{Sr/Cl}_{\text{RF}} = 0.56$ (mean mass ratio
 273 determined from rainfall data; see following section)

274 and F_{EX} is equal to:

$$275 \quad F_{EX} = F_{TF} - F_{RF} \quad (5)$$

276 Assuming that all the Cl flux in throughfall has a sea salt origin, we used $F\text{-Cl}_{TF}$ and X/Cl sea salt ratios
277 ($Na/Cl_{SW} = 0.86$, $Ca/Cl_{SW} = 0.02$, $Mg/Cl_{SW} = 0.10$, $K/Cl_{SW} = 0.02$, $1000Sr/Cl_{SW} = 0.16$ and mass ratio from
278 Brewer et al., 1975) to determine F_{SW} for each cation:

$$279 \quad F_{SW} = F\text{-Cl}_{TF} \times (X/Cl)_{SW} \quad (6)$$

280 and F_{SD} is equal to:

$$281 \quad F_{SD} = F_{RF} - F_{SW} \quad (7)$$

282 The vegetation flux (F_{VEG}) is described by equation 8, where F_{EX} is the flux of cations exuded by plants,
283 and F_{LF} the litter fall flux.

$$284 \quad F_{VEG} = F_{EX} + F_{LF} \quad (8)$$

285 The standing stock of cations in the forest (Stock) is determined from biomass ($376.8 \text{ t}\cdot\text{ha}^{-1}$; Rousteau
286 et al., 2014) and mean cationic concentrations into plants. The residence time (T_{res}) of each element in
287 the vegetation is determined by the following equation:

$$288 \quad T_{res} = \text{Stock} / F_{VEG} \quad (9)$$

289

290 **5. Results**

291 All the compartments of the catchment were characterized for their element concentrations and
292 isotopic compositions. Table 1 presents results of major elements and Sr concentrations only in water
293 samples for which Sr isotopic composition was measured. A full list of the concentrations of major
294 cations we have used in this paper are taken from Clergue et al. (2015) of which the range in

concentrations, means and median values are summarized in Table 2. New trace element and isotopic compositions for solid samples are presented in Table 3.

5.1. Atmospheric samples

The pH of rainfall ranged from 4.1 to 5.7 (Clergue et al., 2015). The major cation in rainfall was Na, whose concentration varied between 41 and 165 $\mu\text{mol/L}$. The mean concentration of K, Ca and Mg were 4, 7 and 12 $\mu\text{mol/L}$, respectively. Sr concentration ranged from 9 and 39 nmol/L (Table 2S) and Sr isotopic composition varied between 0.70841 and 0.71029 (Fig. 2). These data were in agreement with previously published data in the Puerto Rican and Guadeloupean rainforests (Gioda et al., 2013; Dessert et al., 2015).

The concentrations of major elements in Saharan dust collected in Guadeloupe, were higher than those in the soil samples (except for Al and Fe; see Clergue et al., 2015) and lower than in the rock samples (Table 3). The average values for Ca (1830 ppm), Na (940 ppm) and K (5300 ppm) were lower than those reported in the literature for dust samples collected in West Africa (> 2600 ppm for Ca and Na, > 9800 ppm for K; Moreno et al., 2006). Mg concentrations around 5200 ppm were in the range of those reported in the literature (> 4600 ppm; Moreno et al., 2006). The concentration of Sr concentration was around 50 ppm, 1.5 to 5 times lower than the values reported in the literature for dust samples (Moreno et al., 2006) and 10 times higher than soil Sr concentrations. Concerning Sr isotopic data, the dust samples were the most radiogenic of all samples collected on the site. The isotopic signature, around 0.7187, is consistent with previous estimations and measurements (Biscaye et al., 1974; Grousset et al., 1988; Grousset et al., 1992; Rognon et al., 1996) which gave a value of 0.7179 for Saharan dust in the Caribbean (Pett-Ridge et al., 2009b).

5.2. Throughfall samples

The pH of the throughfall was slightly higher than that of the rainfall, ranging from 5.1 to 6.3 (Clergue et al., 2015). The major cation in the throughfall was Na, whose concentration varied between 17 and 264 $\mu\text{mol/L}$ (Table 2). Mean concentration of K, Ca and Mg were 39, 17 and 17 $\mu\text{mol/L}$ respectively. Sr

320 concentration ranged from 8 and 136 nmol/L (Table S2) and Sr isotopic composition varied between
321 0.70953 and 0.70978 (Table 1, Fig. 2). These data were in agreement with the ranges published in the
322 literature for tropical rainforests (e.g. Forti and Neal, 1992; McDowell, 1998).

323 The K/Cl ratio in throughfall was ten times higher than the K/Cl ratio in rainfall, attesting to a strong
324 enrichment of K in throughfall (Fig. 3). To a lesser extent, Sr, Ca and Mg were also enriched in
325 throughfall. The enrichment of throughfall compared to rainfall indicates that these elements are
326 partially released by plants. This exudation process has been largely described in the literature
327 (Vitousek and Sanford, 1986; Dezzio and Chacon, 2006).

328 Throughfall is slightly more radiogenic than sea salt (Fig. 2). This observation can be explained by a
329 mixture in throughfall of sea salt Sr and Sr from Saharan dust leachates or plant exudates. It is
330 impossible to distinguish between the two latter sources only on the basis of Sr isotopes.

331 5.3. Litter samples

332 Major element concentrations in litter samples were very different from concentrations in the other
333 solid samples (Table 3). The most abundant element in the litter was Ca, with concentrations ranging
334 between 1 and 3%. This is more than 100 times the Ca concentration in the soil and is similar to the
335 parent rock Ca concentration. The K concentration, intermediate between 0.1 and 1.1%, and the Mg
336 concentration, ranging between 0.2 and 0.6%, were also higher than the K and Mg concentrations in
337 the soil. These concentrations are consistent with values in the literature for litter samples (e.g. Liao et
338 al., 2006; Riotte et al., 2014). Similarly, the Sr concentration in the litter varied from 80 to 200 ppm,
339 which is one or two orders of magnitude higher than the Sr concentration in the soil (up to 13 ppm).
340 The isotopic signature of the litter varied between 0.70966 and 0.71019 (Fig. 2). This signature differed
341 from the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of local bedrock, but was similar to that of samples of vegetation growing on
342 highly depleted volcanic soil as reported in the literature (Whipkey et al., 2000; Stewart et al., 2001;
343 Chadwick et al., 2009).

344 5.4. Soil solution samples

The soil solutions were acidic, with pH values ranging from 4.2 to 5.4. This can be explained by the low cation content, which plays a key role in neutralizing the acidity of soil solutions. Na and Cl were the most abundant elements, with mean concentrations of 179 $\mu\text{mol/L}$ and 199 $\mu\text{mol/L}$, respectively (Table 2). Average Mg, K and Ca concentrations were 24, 5 and 3 respectively. Sr concentrations in soil solutions ranged between 7 and 101 nmol/L (Table S2), and isotopic composition varied between 0.70996 and 0.71097 (Table 1). Soil solutions were more radiogenic than local rocks and sea salts, attesting to an exogenous source of Sr in the soil solution (Fig. 2). In superficial soil horizons (up to 90 cm), Sr concentrations were systematically higher than in the deeper horizons (mean value of 53 and 16 nmol/L respectively). To a lesser extent, Ca and Mg were also slightly higher in superficial horizons than in the deepest. On the contrary, K concentrations were constant over the entire soil profile.

Fig. 3 shows the cation concentrations normalized to Cl for all dissolved samples. Na/Cl ratios were relatively homogeneous in all water samples and close to the sea salt ratio. In general, soil solutions were depleted in nutrient cations compared to throughfall. This was particularly true for K, which was probably due to efficient K uptake by plant root systems and microorganisms in the first few centimeters of soil. As previously noted, soil solutions of superficial horizons were slightly enriched in Sr, Ca and Mg compared to deeper soil solutions, which indicates a potential atmospheric source of cations. It was even observed that the surface solutions were sometimes enriched in Mg with respect to throughfall.

5.5. Soil and rock samples

The soil profile is characterized by a very high proportion of secondary minerals (95% wt. of secondary minerals and 70 %wt. of kaolinite and halloysite; Buss et al., 2010). The chemical composition of the soil indicated that it was highly depleted in mobile cations compared to unweathered rock in Guadeloupe (Table 3). For example, the Ca concentration varied from 23 to 306 ppm, which corresponds to about 100% depletion compared to volcanic rock, which contains 4.85% to 7.45% of Ca. Sr concentration in soil varied between 2 and 13 ppm and was very low compared to unweathered rock

(Table 3). To correct for dilution effects and volume change, Sr concentration in the soil samples was normalized to an immobile element (Ti). Fig. 4 presents mass transfer coefficient (τ) values for Sr:

$$\tau_{\text{Sr}} = [(Sr/Ti)_{\text{soil}} / (Sr/Ti)_{\text{rock}}] - 1 \quad (10)$$

τ_{Sr} was negative, representing the depletion of Sr in soil compared to unweathered rock. Sr had a depletion rate of around $98 \pm 2\%$. The soil profile was systematically less depleted in its first 15 cm and at depths of 305 cm, 427 cm, 1219 cm and 1250 cm. These depths corresponded to horizons enriched in quartz and K-feldspar.

The entire profile was more radiogenic (0.70677 – 0.71527) than the unweathered volcanic rock sampled in Guadeloupe (Fig. 2 and 4). Quartz horizons exhibited the highest Sr isotopic ratio. This observation attests of exogenic source(s) of Sr to the soil. The ϵ_{Nd} of the profile varied between -8.39 and 2.44 and was different from unweathered rock ranging from 4.34 to 5.45 (Table 3). The Nd signature of the quartz horizons was very negative and attested again of an exogenic contribution of Nd to the profile.

5.6. Quiock Creek water samples

Conductivity in Quiock Creek ranged from 22.5 to 68.2 μS and pH was acidic, ranging from 4.3 to 5.9 (see Clergue et al., 2015). The major cation was Na, with a mean concentration of 234 $\mu\text{mol/L}$. Mean concentrations of K, Ca and Mg were 5, 10 and 29 $\mu\text{mol/L}$, respectively (Table 2). Sr concentration ranged from 35 and 70 nmol/L (Table S2) and Sr isotopic composition varied between 0.70922 and 0.70939.

6. Discussion

6.1. Vegetation cycling

6.1.1. Impact of atmospheric deposits on the cation-nutrient budget

393 A key question is to what extent atmospheric deposition (wet and dry) impacts the forest's nutrient
394 source. Many biogeochemical studies have shown that Sr, and particularly the $^{87}\text{Sr}/^{86}\text{Sr}$ isotopic ratio,
395 is a good tracer of ecosystem Ca sources (e.g. Capo et al., 1998; Bern et al., 2005; Belanger et al., 2012;
396 Stille et al., 2012; Pett-Ridge et al., 2009a). K and Mg chemistry differs from Ca and Sr, but these
397 lithophilic elements ultimately originate from the same sources. It is therefore possible to acquire some
398 qualitative information on the cycles of these elements using Sr as a proxy.

399 The internal water cycle of our basin is relatively homogeneous from a Sr isotopic point of view, with a
400 mean $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.7097 for throughfall and 0.7104 for soil solutions (up to 12 meters deep; Fig.
401 2). This shows that the dissolved pool of Sr is dominated by sea salts ($^{87}\text{Sr}/^{86}\text{Sr}$ value equal to 0.7092),
402 with a small influence of more radiogenic sources coming from Saharan dust leaching (Fig. 2). Note also
403 that the Sr isotopic composition of litter of 0.7099 is in the range of that of the dissolved pool of Sr.
404 This has already been well described in several studies, which have shown that vegetation exhibits the
405 signature of the exchangeable Sr pool (e.g. Kennedy et al., 1998; Poszwa et al., 2002). Our results
406 emphasize that atmospheric inputs contribute significantly to actively cycled Sr in the Quiock Creek
407 basin. This hypothesis is consistent with the literature for similar contexts with highly depleted volcanic
408 soils and strong atmospheric input (e.g. Whiptkey et al., 2000; Stewart et al., 2001; Chadwick et al.,
409 2009; Schuessler et al., 2018). As an example, Pett-Ridge et al. (2009a) reported that the proportions
410 of foliar Sr derived from sea salt and dust vary between 33% and 59% in the Puerto Rican rainforest.
411 Similarly, in the Quiock Creek catchment, the $^{87}\text{Sr}/^{86}\text{Sr}$ of litter is slightly more radiogenic than sea salt
412 aerosols, emphasizing the influence of Saharan Sr on the ecosystem.

413 Based on the Sr isotopic composition, the weathering of local volcanic rock seems not to contribute in
414 the plant Sr pool. It can be deduced that this is also true for the Ca, K and Mg pools. This observation
415 is consistent with the idea that tropical forests developed on highly nutrient-depleted soils derive their
416 nutrients from superficial atmospheric sources and from litter recycling (Jordan, 1982). It may be for
417 this reason that surface soil solutions are slightly less depleted in cations than deeper solutions (>91
418 cm; Fig. 3), reflecting the cationic inputs of throughfall, dust leaching/weathering and litter

remineralization. We also suggest that a little near-surface nutrient pool sustains the forest community of Quiock Creek.

Tropical forests are largely described as dependent on atmospheric sources, as observed in this study, but they are also known to recycle nutrients very efficiently. In the following section, we calculate the vegetation fluxes in the catchment and estimate the cation-nutrient recycling fluxes.

6.1.2. Vegetation cycling at the soil-plant profile scale

Nutrients contained in plants are released during leaf excretion, litter leaching and litter decomposition. These bio-available elements are partly taken up by the vegetation from the soil solution and, therefore, are recycled. The proportion of nutrients recycled by plants depends on the amounts of available nutrients in the soil. As an example, the study by Holmden and Belanger (2010) shows that in a Boreal forest ecosystem, the proportion of recycled Ca from litter fall can represent from 80% and 90% of the annualized Ca inputs to the forest Ca cycle. The authors also note that the proportion of recycled Ca increases with decreasing weathering flux.

The internal-cationic fluxes calculated in the Quiock Creek catchment are summarized in Table 4 and Fig. 5. The vegetation flux (FVEG) varies between $8.4 \text{ kg} \cdot \text{ha}^{-1} \cdot \text{yr}^{-1}$ for Na and $141.5 \text{ kg} \cdot \text{ha}^{-1} \cdot \text{yr}^{-1}$ for Ca and represents the biggest elemental flux, except for Na. These results are in agreement with those of the review by Proctor et al. (1987) on primary rainforests and the study by McDowell (1998) in a Puerto Rican rainforest. For Ca, Mg and Sr, most of the vegetation flux is provided by litter fall. Concerning K, its flux provided by leaf excretion ($41.2 \text{ kg} \cdot \text{ha}^{-1} \cdot \text{yr}^{-1}$) is twice as abundant as the litter fall flux ($20.9 \text{ kg} \cdot \text{ha}^{-1} \cdot \text{yr}^{-1}$). This confirms that canopy leaching is the main source of K for the top soil (e.g. McDowell 1998; Riotte et al., 2014). Finally, the Na flux released by vegetation is relatively weak compared to rainfall flux. Na is not a nutrient for plants and it exhibits conservative behaviour when rainwater passes through the canopy. We note that for Sr, K, Ca, and, to a lesser extent Mg, plant recycling is highly efficient. The vegetation flux (FVEG) of Sr, K, and Ca are respectively, 20, 28 and 31 times greater than flux exported at the outlet of the basin (FQC). The vegetation flux of Mg is 3 times greater than the flux

444 exported by the Quiock Creek. This vegetation turnover efficiency is related to the degree of soil
445 leaching and thus the nutrient pool derived from weathering minerals. In the tropical context of our
446 study, it is not surprising to observe such a high turnover, because of the nutrient paucity in soils. The
447 same range of solute turnover has been measured in the tropical watershed of Mule Hole in India
448 (Riotte et al., 2014), where vegetation recycling fluxes represented 10-15 times the exported fluxes.
449 More recently, in a tropical watershed in Sri Lanka, Schuessler et al. (2018) estimated this recycling
450 factor between 2 and 7 for Mg, 3 and 10 for Ca and 9 and 29 for K.

451 Rousteau et al. (2014) have shown that vegetation in the Quiock Creek catchment is at equilibrium with
452 respect to carbon. If the ecosystem is close to equilibrium, the nutrient fluxes taken up would be equal
453 to FVEG (litter fall + leaf excretion). Numerous studies (e.g. Proctor, 1987) have shown that in tropical
454 rainforests, decomposition is invariably rapid and that litter turnover takes less than a year. Even though
455 we did not measure the decomposition rate of litter, our field observations confirm the speed of this
456 process. From the standing stocks of cations in the forest and the annual-cationic FVEG fluxes (Table
457 4), we determined the residence time (T_{res}) of each element in the vegetation. The element presenting
458 the shortest residence time in the vegetation is K, namely 16 years. This residence time is consistent
459 with the 10 year period determined for K in Puerto Rican forest (McDowell 1998). This short residence
460 time is justified by the fact that K is one of the most important elements for plant metabolism (as a
461 catalytic agent for carbohydrate synthesis and the transfer of other nutrients) and is abundantly
462 excreted by the leaves. For other elements, the residence time is slightly longer than those determined
463 for K: 44.6 years for Sr, 44.9 for Ca, 45.7 for Mg and 48.2 for Na. These results highlight that vegetation
464 recycling dominates the nutrient cycle, and, in light of the Sr isotopic signature, we can deduce that
465 these nutrients have the particularity of being initially of atmospheric origin. Therefore, the Quiock
466 Creek ecosystem is sustained by a little near-surface nutrient pool, which seems disconnected from the
467 deep bedrock.

468 Our study is a first step in the characterization of biogeochemical cycles at the plant-soil scale in the
469 Guadeloupean rainforest. To better characterize and quantify the nutrient recycling, it would be useful

470 for example, to study the seasonality of vegetation fluxes, investigate the N and P cycles, or use the
471 isotopic fractionations of the elements involved in these biogeochemical processes (Ca, Mg, Si, B,...).

472 6.2. Soil cation-nutrient pool and weathering

473 6.2.1. Origin of cation-nutrient pool in the soil

474 After studying geochemical cycles at the plant-soil scale, it is necessary to study the soil profile to
475 determine whether soil is still able to provide nutrients to the forest.

476 In the entire soil profile (Fig. 2), the Sr isotopic signature of the solid phase is high relative to rock,
477 which is consistent with exogenous contributions of Sr. Fig. 6 presents the Sr isotopic signature of soil
478 as a function of the Sr depletion rate (τ_{Sr}). The more the sample is rich in Sr, the more the soil Sr
479 signature is radiogenic. This implies that the main source enriching the soil in Sr is more radiogenic than
480 bedrock. The two potential sources of Sr that could enrich the soil in radiogenic Sr are: 1) Sea salts with
481 a signature of 0.70917 (Dia et al., 1992) or 2) Saharan dust with a signature of 0.7187 (this study). This
482 indicates that the soils are so leached that they have almost lost their original rock signature and have
483 inherited an exogenous atmospheric signature. As previously discussed (Section 5.5) at depths of 15,
484 30, 305, 427, 1219 and 1250 cm, the high $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (> 0.712) are correlated with the highest
485 primary mineral content (Quartz + Feldspar), which could correspond to different dust deposit
486 horizons. All the other soil samples are not enriched in primary minerals but, nevertheless, are
487 characterized by Sr isotopic ratios that indicate a mixture of bedrock and exogenous atmospheric
488 sources. This indicates that Sr derived from atmospheric deposits is transferred to the soil exchangeable
489 pool and may be incorporated into secondary minerals. This recycled Sr in the soil exchangeable pool
490 could be taken up by plants and reinforces the hypothesis that the nutrients involved in the Quiock
491 Creek ecosystem are of atmospheric origin. This strong atmospheric influence on the soil profile has
492 been described in the study by Clergue et al. (2015), devoted to Li dynamic in the same catchment. The
493 $\delta^7\text{Li}$ measured in the soil profile also indicated that atmospheric deposition (wet and dry) was a main
494 source of Li in the bulk soil.

495 Because both wet and dry atmospheric deposits are sources of radiogenic Sr, it is not possible to
496 discriminate between sea salt and Saharan sources in soil only on the basis of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio.
497 Coupled with Sr isotopes, Nd isotopes are useful for identifying the different contributions to the soil
498 profile. For example, ϵNd of rock ranges from 4.34 to 5.45 (Table 3) and ϵNd of Saharan dust ranges
499 from -10.5 to -14.5 (Grousset et al., 1992; Dia et al., 2006; Scheuven et al., 2013; McClintok et al.,
500 2015). Sea salt exhibits an extremely low Nd concentration and Saharan dust input seems to be the
501 only atmospheric contribution able to shift the isotopic composition of the soil. The Nd isotopic
502 composition of soil varies between -8.39 and 2.71 and could be explained by a mixture of rock and dust
503 endmembers. The quartz-feldspar horizons are characterized by very negative ϵNd , indicating a strong
504 Saharan Nd contribution. The amount of quartz and Nd isotopes provide two independent proxies of
505 long-term dust additions to the soil profile. The superficial horizon (the first 30 centimetres) is a
506 contemporary depositional surface while the other horizons attest to past deposition. The deepest
507 quartz horizons (305, 427, 792 and 1219-1250 cm) may represent paleo-surfaces of dust deposits,
508 interspersed between multiple events of volcanic deposition. The variable thickness of these horizons
509 may be partly explained by a physical soil mixing process resulting from bioturbation.

510 In Fig. 7, the soil samples are plotted in a two-component mixing diagram for $^{87}\text{Sr}/^{86}\text{Sr}$ versus ϵNd . The
511 curvature of the different mixing lines depends on the Sr/Nd ratio of each endmember. The dotted
512 curve represents the mixing line between the unweathered rock endmember ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7038$, ϵNd
513 $= 4.8$, $\text{Sr}/\text{Nd} = 17.9$; from this study and the andesite Nd content of 16 ppm from Taylor and McLennan
514 1985) and the Saharan endmember ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7187$, $\epsilon\text{Nd} = -11.5$, $\text{Sr}/\text{Nd} = 3.4$; from this study and
515 Grousset et al., 1998). This mixing line cannot explain the isotopic composition of the soil samples,
516 indicating that dust is not mixed with fresh rock but with a Sr-depleted weathered rock. Four mixing
517 lines with depleted rock endmembers are shown on Fig. 7. Their Sr/Nd ratios decreased from 10 to 0.1
518 in the most depleted case.

519 If we first consider soil horizons enriched in quartz-feldspar, this mixing model confirms that these
520 particular layers are strongly influenced by the dust endmember. It also emphasized that the

521 proportion of Saharan Sr in the soil decreases with depth, from 65% in the first 15 cm, to 20% in the
522 deepest quartz-feldspar horizons. Finally, our results show that the degree of rock depletion also
523 increases with depth. Indeed, surface horizons (15 and 30 cm) can be explained by mixing of dust with
524 moderately depleted rock ($10 < \text{Sr}/\text{Nd} < 5$) whereas the deeper horizons involve a mixture with a very
525 depleted rock ($\text{Sr}/\text{Nd} < 1$). The superficial volcanic rock signature is inherited from the deposit of volcanic
526 ashes in Guadeloupe linked to very recent activity of neighbour volcano Soufriere Hills on Montserrat
527 (Baxter et al., 1999; Cadelis et al., 2013). The accumulation of Saharan dust in the upper soil is also
528 observed in quartz-diorite and volcanoclastic soils in Puerto Rico (McClintock et al., 2015), which is too
529 far from the volcanic arc of the Lesser Antilles to be impacted by recent ash deposits. In Puerto Rico,
530 the calculated soil dust content ranges between 0 and 8%, and Nd from dust in the upper 20 cm of soil
531 ranges between 0 and 92% (McClintock et al., 2015), which is consistent with what we have observed
532 in Guadeloupe.

533 If we now consider soil horizons non-enriched in quartz-feldspar, we note that their isotopic
534 composition still reflects a slight influence of the dust endmember and that they have $^{87}\text{Sr}/^{86}\text{Sr}$ ratios
535 close to those of rainfall or that are slightly more radiogenic. The rock Sr isotope signature in these
536 horizons has been completely overprinted by the atmospheric signature (rainfall and dust-derived Sr).
537 The slight influence of dust on the Nd signature in the entire soil profile is clear evidence for the
538 mobilization of dust-derived Nd and its redistribution in the soil. This is especially the case for the
539 horizons at depths of 61 and 91 cm, which do not contain quartz and feldspar, but whose Sr and Nd
540 isotope signatures are strongly influenced by the dust endmember (25 to 35%). It is possible that the
541 Sr and Nd come from the leaching of Saharan minerals contained in the upper soil and that are
542 reincorporated into the deeper soil levels. Even if Nd mobility is much lower than Sr mobility, it seems
543 to increase under extreme leaching conditions. This mobilization of dust-derived Nd into highly
544 weathered soil profiles has been observed in Puerto Rico, where the Nd isotope signature of Saharan
545 dust has been observed noted at depths of 2 and 3 m (Pett-Ridge et al., 2009b). Our mixing model
546 cannot explain all the data because of the influence of a third end-member, namely sea salt Sr derived

from rainwater. Because sea salts are not a significant source of Nd, the addition of sea salts does not influence the Nd isotopic composition of soil. Except for the dust horizons, andesitic and dust-derived Sr have been leached extensively and the sea salt Sr signature dominates in the entire profile.

In the Quiock Creek catchment, we observe a strong impact of atmospheric sources on the evolution of the chemical composition of the soil with depth and with time. Elements are continuously provided at the surface by fresh dust minerals on a highly depleted soil. Then, we observe a “reversed” weathering profile, with the horizon the most enriched in primary minerals (Saharan and volcanic) and having the strongest andesitic isotopic signature at the top of the soil profile. The impact of atmospheric sources on volcanic soil has been demonstrated in different tropical contexts. In a soil chronosequence in Hawaii, it was shown that the older the soils, the bigger the impact of atmospheric inputs (Kennedy et al., 1998; Whiptkey et al., 2000; Kurtz et al., 2001; Chadwick et al., 2009). Saharan dust was shown to affect soil composition in Puerto Rico (Pett-Ridge et al., 2009b; McClintock et al., 2015) and in Mount Cameroon (Dia et al., 2006). In Guadeloupe, Mg and Li isotopes reflect the influence of sea salt and dust on soil (Opfergelt et al., 2012; Clergue et al., 2015; Fries et al., 2019). Our study supports these prior observations and the need to fully account for these inputs when studying weathering and cation-nutrient cycling under tropical climatic conditions.

6.2.2. Does chemical weathering provide elements to the catchment flux?

The comparison between rainfall fluxes and output flux from Quiock Creek provides information on processes taking place in the soil. Elementary budgets (output flux – input flux) are negative (Fig. 5). This may mean that the catchment stores cation nutrients in the soil or in the vegetation. However, it can also mean that for these elements, inputs from rainfall are underestimated. In fact, their mean concentrations in rain are highly variable and hard to estimate. In any case, it means that these elements are not enriched as they move through the soil and thus there is no weathering flux for these elements in the catchment. The Sr isotopic composition of Quiock Creek, which is close to the sea salt aerosol signature, supports the idea that the Sr comes from atmospheric input only (Fig. 5). The fact

572 that the Quiock Creek $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is very different from the volcanic rock signature, indicates that
573 the local rock no longer contributes to the weathering flux. The absence of weathering flux in the
574 Quiock Creek catchment and its peculiar Sr isotopic composition are linked with the intense weathering
575 of the soil, which is highly depleted in major elements (Clergue et al., 2015). This situation is peculiar
576 in Guadeloupe, as in all other catchments studied, the weathering flux is equivalent, or even twice as
577 high, as the rainfall flux (Dessert et al., 2015). This situation is also peculiar in the Caribbean, for
578 example in Puerto-Rico, where numerous catchments are surveyed by the USGS. In the Puerto-Rican
579 catchments, which are subject to the same climate and are covered by rainforest, soils are not as
580 depleted as in Guadeloupe (e.g. Ferrier et al., 2010). The Rio Icacos basin in Puerto Rico is the site of
581 the highest measured chemical solute fluxes for a catchment on granodiorite (Turner et al., 2003).

582 Clergue et al. (2015) showed that in this catchment, part of the weathering flux of Li originates from
583 the main secondary mineral dissolution (i.e. kaolinite). Using the kaolinite dissolution rate (Carroll et
584 al., 1988), the authors showed that kaolinite dissolution can explain the weathering flux of Li measured
585 on site. The same calculations were made for Mg and Sr, using the average concentration of those
586 elements in kaolinite. They show that kaolinite can provide Mg and Sr by dissolution, with a respective
587 flux of $0.012 \text{ kg}_{\text{Mg}} \text{ ha}^{-1} \text{ yr}^{-1}$ and $0.002 \text{ kg}_{\text{Sr}} \text{ ha}^{-1} \text{ yr}^{-1}$. However, these fluxes are much lower than the
588 rainfall fluxes and consistent with the absence of measurable weathering flux for some major elements
589 and Sr.

590 7. Conclusion

591 In the Quiock Creek catchment, a large range of $^{87}\text{Sr}/^{86}\text{Sr}$ and ϵNd values is observed despite the small
592 scale of observation. Sr isotopic composition varies from 0.70677 in deep bulk soil samples to 0.71882
593 in dust samples. The Nd isotopic composition varies just as much, between -8.39 in near-surface soil
594 samples to 2.71 in deeper soil (732 cm depth). For the Saharan dust endmember, we used a mean ϵNd
595 value of -11.5, determined from the literature. These large isotopic ranges, coupled with major and
596 trace elements, have helped to better understand nutrient dynamic in tropical ecosystems in
597 Guadeloupe.

598 The regolith profile was built on pyroclastic deposits, but, because of extreme leaching, it has almost
599 lost its original andesitic signature and inherited an exogenous atmospheric signature. Only Saharan
600 dust is likely to have influenced the Nd balance throughout the entire 12m-thick profile, while the Sr
601 balance is influenced by both Saharan dust and sea salt aerosols. Sr and Nd isotopes, combined with
602 mineralogy and mobile element concentrations in the regolith, argue for a multi-layered soil profile
603 which has been built by successive volcanoclastic episodes, separated by periods of dust deposition.
604 Deep horizons enriched in quartz-felspar are then interpreted as paleo-soils impacted by Quaternary
605 Saharan dust deposits, whereas the near-surface soil horizon is currently impacted by fresh dust
606 deposits. Our results show that only the chemical weathering of the near-surface fresh minerals can
607 provide nutrients to the ecosystem, the deeper regolith (> 30 cm) being nutrient depleted. However,
608 this dust weathering flux is too low to sustain the tropical forest ecosystem.

609 The cationic mass balance at the catchment scale and the Sr isotopic signature of Quiock Creek indicate
610 that cation and Sr fluxes are of atmospheric origin. Thus, in this highly weathered catchment, the
611 original andesitic bedrock no longer participates in the weathering fluxes of Quiock Creek. This
612 conclusion leads us to question the notion of “bedrock” in catchment involving on a deep weathered
613 formation. Is it still an andesitic bedrock or is it now a lateritic bedrock?

614 The dissolved Sr cycle at the catchment scale is mainly dominated by sea salts, with a small contribution
615 of Sr coming from the Saharan dust leaching. The vegetation exhibits the signature of the dissolved
616 pool of Sr, indicating that the nutrient pool derives from atmospheric inputs.

617 At the soil-plant scale, the cation-nutrient fluxes provided by vegetation (litter fall + leaf excretion) are
618 major compared to input and output fluxes. The Ca, K, Sr and Mg fluxes each year in the vegetation
619 are, respectively, 31, 28, 20 and 3 times greater than the exported fluxes at the outlet of the basin. The
620 residence time of nutrients in vegetation is 16 years for K and close to 45 years for Sr, Ca and Mg. These
621 results emphasize the highly efficient plant turnover that dominates the nutrient cycle in the Quiock
622 Creek catchment.

623 This first characterization of biogeochemical cycles in a Guadeloupean forest suggests that the forest
624 community of Quiock Creek is sustained by a small near-surface nutrient pool, disconnected from the
625 deep andesitic bedrock.

626

627 **Acknowledgements**

628 This work has been financially supported by the INSU-CNRS and the Région Guadeloupe. Parts of this
629 work were supported by the IGP multidisciplinary program PARI and by the Paris-IdF region SESAME
630 Grant no. 12015908. This work could not have been done without logistical support from 1) both INSU-
631 CNRS observatories in Guadeloupe run by the IGP: the Observatoire de l'Eau et de l'Erosion aux
632 Antilles (OBSERA) and the Observatoire Volcanologique et Sismologique de Guadeloupe (OVSG) and,
633 2) the Parc National de Guadeloupe (PNG). We thank in particular N. Liagre, M. Valy and F. Bastaraud
634 from PNG for their assistance with the field work. We also thank X. Quidelleur and P. Lahitte (Paris Sud
635 11 University) for providing us with rock samples from Guadeloupe. Major element concentrations
636 from water and solid samples were measured by L. Cordier and C. Gorge. Thanks are extended to B.
637 Caron from IsTeP-UPMC and J.-L. Birck, A. Cogez, L. Faure, A. Michel, M. Tharaud from IGP for their
638 analytical assistance. The equipment and services of the Laboratoire de biologie et de physiologie

639 végétale de l'Université des Antilles was used for the biological and ecological aspects of the study. We
640 thank M. Daullet for his assistance in the laboratory. Special thanks to V. Virapin, who processed and
641 weighed most of the collected litter samples and E. Mira who made and placed the litter traps. This
642 study greatly benefited from comments from A. Cogez, M. Dulormne, F. Bussière, J. Molinié and R.
643 Losno. We gratefully acknowledge Susan Johnson for her helpful comments on the original version of
644 this paper. We have a special thought for our colleague and friend Agnès Michel, who passed away in
645 2018. She was involved in the solid sample analyses and was always keen to develop new analytical
646 experiments. We gratefully acknowledge two anonymous reviewers and the editor for their helpful and
647 critical comments on the original manuscript. IGP contribution # 4079.

858 Figure caption

859 Fig. 1. The Quiock Creek catchment (16°17'N, 61°70'W) in the Guadeloupe National Park. The MF rain
860 gauge is located in a clearing, on the roof of the “Maison de la Forêt”, and the OVSG rain gauge is
861 located on the roof of the observatory. The soil profile was sampled during lysimeter installation (see
862 Buss et al., 2010).

863 Fig. 2. Sr isotopic composition of dissolved and solid samples collected in the Quiock Creek catchment.
864 Sea salt Sr isotopic ratio = 0.70917 (Dia et al., 1992); volcanic rock = 0.7038 (this study); Saharan dust
865 = 0.7187 (this study).

866 Fig. 3. Molar ratios ($\mu\text{mol}/\mu\text{mol}$ ratios, except for the Sr/Cl ratio expressed in $\text{nmol}/\mu\text{mol}$) of dissolved
867 load in the different compartments of the Quiock Creek catchment. RF: rainfall, TF: throughfall, SS: soil
868 solution (above and below 91 cm depth), QC: Quiock Creek, SW: seawater/sea salt.

869 Fig. 4. Soil profiles. Quartz + feldspar content (from Buss et al., 2010), mass transfer coefficient (τ) for
870 Sr in soil samples relative to bedrock, and isotopic signature of Sr and Nd. τ is calculated considering Ti
871 to be immobile and illustrates the extreme depletion of Sr in the soil compared to unweathered rock
872 (values closed to -1).

873 Fig. 5. Cation fluxes in the Quiock Creek catchment expressed in $\text{kg}/\text{ha}/\text{yr}$. FSW is the sea salt flux, FSD
874 the Saharan dust leaching flux, FRF the rainfall flux, FTF the throughfall flux, FLF the litter fall flux, FEX
875 the leaf excretion flux and FQC the Quiock Creek flux.

876 Fig. 6. Sr mass transfer coefficient as a function of Sr isotopic ratio in soil samples. Sea salt Sr isotopic
877 ratio = 0.70917 (Dia et al., 1992); volcanic rock = 0.7038 (this study); Saharan dust = 0.7187 (this study).
878 Samples enriched in quartz-feldspar are symbolized by white square.

879 Fig. 7. Two-component mixing diagram of ϵNd vs. Sr isotopic ratio in soil samples. Horizon depths (cm)
880 are added and samples enriched in quartz-feldspar are symbolized by white squares. The solid lines

881 represent different mixing curves between a bedrock (fresh and depleted) end-member and a “Saharan
882 dust” end-member. The mixing proportions are expressed in % of dust Sr. The black dotted curve
883 represents a mixture of fresh rock ($^{87}\text{Sr}/^{86}\text{Sr} = 0.7038$, $\epsilon\text{Nd} = 4.8$, $\text{Sr}/\text{Nd} = 17.9$) and dust ($^{87}\text{Sr}/^{86}\text{Sr} =$
884 0.7187 , $\epsilon\text{Nd} = -11.5$, $\text{Sr}/\text{Nd} = 3.4$). The other curves show a mixture between of depleted rock ($^{87}\text{Sr}/^{86}\text{Sr}$
885 $= 0.7038$, $\epsilon\text{Nd} = 4.8$, Sr/Nd varying from 10 to 0.1 for the most depleted rock) and dust. The samples
886 are explained by a mixture of Saharan dust and depleted rock. The soil horizons enriched in quartz-
887 feldspar are strongly influenced by dust (20 to 65% of dust Sr). The near-surface horizon (first 30 cm) is
888 the most impacted by dust and can be explained by the mixing of dust with moderately depleted rock.
889 This emphasizes the contemporary, or very recent, deposition of both Saharan dust and volcanic ash in
890 Guadeloupe (recent volcanic activity of nearby Montserrat). The deeper quartz-feldspar horizons are
891 paleo-surfaces of dust deposits interspersed with volcanic deposits. With time, andesitic and dust-
892 derived Sr has been leached extensively and the sea salt Sr signature dominates today in the entire
893 profile.
