ABSTRACT

The identification of parameters of spatially variant blurs given a clean image and its blurry noisy version is a challenging inverse problem of interest in many application fields, such as biological microscopy and astronomical imaging. In this paper, we consider a parametric form for the blur and introduce a state-space model that describes the statistical dependence among the neighboring kernels. Our Bayesian approach aims at estimating the posterior distributions of the kernel parameters given the available data. Since those posteriors are not tractable due to the nonlinearities of the model, we propose a sequential Monte Carlo approach to approximate the distributions by processing the data in an online manner. This allows to consider numerous overlapped patches and large scale images at reasonable computational and memory costs. Moreover, it provides a measure of uncertainty due to the Bayesian framework. Practical experimental results illustrate the good performance of our novel approach, emphasizing the benefit to exploit the spatial structure for an improved estimation quality.

Index Terms— Blur identification; spatially variant blur; Bayesian estimation; particle filtering.

1. INTRODUCTION

Optical instruments often produce images that suffer from blur due to light diffraction or object motion, among many other causes. The presence of the blur provokes an infinitely point-source to be spread in the acquired image defining the so-called Point Spread Function (PSF). Several computational strategies have been proposed in the literature for first estimating and then removing the blur in acquired images [1, 2], or for jointly estimating both image and blur with a blind deconvolution strategy [3]. Obviously, the performance of the deblurring step strongly depends on the accuracy of the PSF estimation. An efficient strategy for this estimation relies on a preliminary acquisition step of normalized and calibrated objects, such as fluorescent spherical microbeads in microscopy [4] or resolution charts in digital camera calibration [5, 6]. Then, the problem is formulated as a linear system that can be inverted efficiently with penalized optimization strategies [7, 8]. The result can finally be fitted in a parametric non-linear model of the PSF in order to uncover characteristics of the optical system [9, 10, 11].

In most realistic scenarios, the PSF cannot be considered constant throughout the field-of-view due to various reasons such as defocus [12, 13], moving objects or cameras [14], anisotropic optical lens aberrations [15], or atmospheric turbulence [16, 17]. This non-stationary behavior gives rise to the so-called spatially variant blur [18]. This blur is much harder to estimate since the associated PSFs need to be recovered at each location in the spatial plane. This also induces a critical increase of computational complexity for identifying and removing the blur [7, 19, 20], and approximation strategies must often be employed to limit the cost of the blur operator [21, 22, 23].

In this paper, we focus on the problem of identifying the parameters of spatially variant PSFs from calibrated image acquisitions. We consider a parametric form for the blurs and formulate the problem of estimating the parameters as a state-space model assuming a smooth variation of the PSF shapes from neighboring regions. Since the resulting state-space model is nonlinear, we choose a particle filtering approach and its backward-simulation smoother to approximate the filtering and the smoothing posterior distributions, respectively. Our approach processes in an online manner a sequence of possibly overlapped patches extracted from the acquired image, and provides a probabilistic estimate of the kernel parameters at the corresponding patch locations. The Bayesian framework brings three key features, namely (i) limited computational cost and memory load thanks to an online processing, (ii) an explicit quantification of the statistical uncertainty on the estimated parameters, and (iii) a remarkable flexibility in the choice of the state-space models, allowing to account for non-linear relations and non-Gaussian noise. As an example, we propose a specific state-space model that accounts for smooth variations in scale and orientation along the neighboring kernels. We illustrate the efficiency and good performance of the approach by means of two sets of numerical experiments.

The rest of the paper is organized as follows. Section [2]
introduces the problem of spatially variant blur identification. Section 3 presents our algorithm for Bayesian inference, and introduces a specific state-space model for parametric PSF estimation. Section 4 illustrates the performance of the proposed approach, and Section 5 concludes the paper.

2. PROBLEM STATEMENT

Let us consider the observation of two images \((x, y) \in \mathbb{R}^N\), where \(x\) is the clean image and \(y\) is a blurry noisy version of it. Blur identification aims at estimating the parameters of the blur model that allows to describe the relationship between \(x\) and \(y\), accounting for the presence of noise. In this paper, we consider the case of spatially variant blurs. More precisely, let us decompose each image \(x \in \mathbb{R}^N\) into \(T\) possibly overlapping patches \((x_t)_{1 \leq t \leq T} \in \mathbb{R}^P\). We assume that, for each patch index \(t \in \{1, \ldots, T\}\),

\[
y_t = X_t h_t + n_t, \tag{1}
\]

where \((y_t)_{1 \leq t \leq T} \in \mathbb{R}^P\) is the set of blurry noisy patches, \((n_t)_{1 \leq t \leq T} \in \mathbb{R}^P\) models the additive noise. Hereabove, \((X_t)_{1 \leq t \leq T} \in \mathbb{R}^{P \times L}\) are suitable block circulant matrices related to \(x\), which encode 2D convolutions with circular boundaries padding with \((h_t)_{1 \leq t \leq T} \in \mathbb{R}^L\), the unknown blur kernels associated with each patch localization. The goal is thus to estimate the set of kernels \((h_t)_{1 \leq t \leq T}\), given the inputs \((y_t, X_t)_{1 \leq t \leq T}\). In this work, we will consider a parametric model for the blur kernels given by

\[
(y \in \{1, \ldots, T\}), \quad h_t = h(\rho_t), \tag{2}
\]

where \(h\) is a known function describing the general 2D shape of the kernels, parametrized by \((\rho_t)_{1 \leq t \leq T} \in \mathbb{R}^K\), \(K \geq 1\). For instance, a defocus blur can be described using a circular function parametrized by its radius \(r\), while uniform motion blur can depend on length and rotation parameters \(\theta\).

This parametric model can also encompass the widely used Gaussian blur shape \(G(\rho)\) that we will retain for our experiments. More sophisticated parametric models can be found for instance in \(\text{[27]}\). In the following section, we will propose a versatile filtering strategy for approximating the posterior distribution of \((\rho_t)_{1 \leq t \leq T}\), while allowing for an efficient online treatment of the inputs \((y_t, X_t)_{1 \leq t \leq T}\). Then, we will discuss a useful example of state-space model to describe the statistical dependencies of the vector of parameters \((\rho_t)_{1 \leq t \leq T}\).

3. PROPOSED METHOD

3.1. Bayesian inference in state-space models

Let us assume a Markovian dependency among the kernels, described by the state-space model

\[
p(\rho_0), \quad p(\rho_t | \rho_{t-1}), \quad p(y_t | \rho_t, X_t), \tag{3}
\]

</table>

where \(p(\rho_0)\) is the prior distribution of the state, \(p(\rho_t | \rho_{t-1})\) is the state model, and \(p(y_t | \rho_t, X_t)\) is the observation model. Our goal consists in estimating probabilistically the unknown parameters of the model. In the sequential processing approach, we build the sequence of filtering posterior distributions given the processed data up to patch index \(t\), \((p(\rho_t | X_{1:T}, y_{1:T}))_{1 \leq t \leq T}\) and the sequence of smoothing posterior distributions given all dataset \((p(\rho_t | X_{1:T}, y_{1:T}))_{1 \leq t \leq T}\). Unfortunately, for most realistic state-space models, these distributions cannot be obtained analytically, and one needs to resort to approximations. Table 1 describes the sequential Monte Carlo approach for estimating those distributions. Step 2 implements the filtering mechanism, and in particular we describe the bootstrap particle filter (BPF) algorithm. In Step 3, we implement the backward-simulation (BS) smoother to approximate the smoothing distribution, given all filtering distributions. Note that, without loss of generality, we have considered the BPF (arguably the most popular particle filter implementation \(\text{[28]}\)) and the simple BS smoother, but other advanced filters could be employed instead \(\text{[29, 30, 31]}\). As a result of the BPF, for each patch \(t\), we can approximate the filtering distribution \(p(\rho)_{1 \leq m \leq M}\) by the \(M\) generated particles \((\tilde{\rho}^{(m)}_t)_{1 \leq m \leq M}\) and associated normalized weights \((w_t^{(m)})_{1 \leq m \leq M}\) computed in Step 2(a)-(b). Moreover, the BS step allows to approximate the smoothing posterior distributions \((p(\rho_t | X_{1:T}, y_{1:T}))_{1 \leq t \leq T}\) by \(S\) equally weighted
sampled particles \((\rho_i^{(1)}(s(t)))_{1 \leq s \leq S}\) given by Step 3(b).

3.2. State-space model for the PSF variation

Let us now present a specific model for the evolution of the parameters \((\rho_i)_{1 \leq i \leq T}\) along the patches, which relies on the assumption that the PSFs of two neighboring patches only differ by a small change in their scale and orientation. More precisely, let us consider that function \(h(\cdot)\) takes as an input a vector of three parameters \((\theta, s)\). The parameter \(\theta \in \mathbb{R}\) defines the orientation while \(s \in (0, +\infty)^2\) quantifies the width of the PSF. This model allows for instance to encompass the family of centered Gaussian blur kernels parametrized by a covariance matrix \(C(\theta, s) = R_\theta \text{Diag}(s)R_\theta^T\) with \(R_\theta \in \mathbb{R}^{2 \times 2}\) denoting the rotation matrix with angle \(\theta\). We then propose the following Markov model for \((\rho_i)_{1 \leq i \leq T}\) to quantify the gain of exploiting the spatial structure of the problem, we compare the filtering and smoothing posteriors with the posterior distribution \(p(\rho_i | X_i, y_i)\), approximated by an importance sampling (IS) strategy. We also compare with an approach based on the maximum a posteriori (MAP) estimator of \((\bar{h}_i)_{1 \leq i \leq T}\) that promotes space-varying blurs with smooth variations, satisfying simplex constraint [56, 7]. Note that no parametric model is assumed in that case. More precisely, a penalized least squares loss function, accounting for simplex constraints as well as 2D spatial regularity, is formulated, and minimized using FISTA algorithm [37].

The performance of all methods are evaluated in terms of the root mean squared error (RMSE) averaged over patches, i.e., \(\text{RMSE} = \frac{1}{T} \sum_{t=1}^{T} \frac{\|\bar{h}_t - \bar{h}_t\|_2}{\|\bar{h}_t\|_2}\) where \(\bar{h}_i\) and \(\bar{h}_i\) are respectively the original and estimated kernel also promotes a spatially-varying blurs at patch \(t\) more precisely, \(\bar{h}_i = h(h_i, \tilde{s}_i)\) with \(\tilde{h}_i\) and \(\tilde{s}_i\) the mean estimators of the angle and scale parameters for BPF, BPF-BS and IS, while \(\bar{h}_i\) is the MAP estimator at patch \(t\), for the MAP approach. Note that BPF, BPF-BS, and IS approximate the whole distribution of the patch parameters, so any other moment of the distribution could be computed, contrasting with the MAP strategy.

All the presented results are averaged over 100 runs. We conduct the numerical experiments in a Matlab environment on a computer with an Xeon(R) W-2135 processor (3.7 GHz clock frequency) and 12 GB of RAM.

4.2. Numerical results

In our first set of experiments, parameters \((\theta_i, s_i)\) for \(1 \leq i \leq T\) are generated following the transition model in Section 3.2 with \(T = 64\) non-overlapped patches, \(\sigma_\theta = \sigma_s = 0.1, s_{\text{min}} = 0.01\) and \(s_{\text{max}} = 0.5\). Two noise levels are consid-
ered, namely \( \sigma_n \in \{0.01, 0.1\} \). Table 2 presents the averaged RMSE for all tested methods. A first observation is that BPF, BPF-BS and IS appear superior to the MAP approach in terms of accuracy, probably because they account explicitly for the parametric shape of the blur. Note that the former methods are also faster. In this example, the running time for MAP is 160 seconds, 10 seconds for BPF and IS and 22 seconds for BPF-BS. The poor performance of IS illustrates that adding the information of the spatial structure improves the inference task. Finally, the smoothing procedure increases the quality of the estimates, at the expense of an extra pass on the dataset and hence a slight increase of computational time. Figure 2 displays, for a specific run, the true parameters (blue circles), the mean of the posterior approximated by BPF (red crosses) and BPF-BS (green crosses), and the error bars showing the mean plus/minus two standard deviations approximated by BPF (red lines) and BPF-BS (green lines). The figure not only shows the great tracking ability of both filtering/smoothing methods but also the uncertainty quantification (note that in patches where the estimation is not as good, the error bars are also wide). One can notice that BPF-BS has improved estimates for the first patch when compared to the BPF thanks to the backward-simulation smoothing process.

In the second setup, the scale and orientation parameters of the kernels are generated using realistic optical models. Two spatially variant models described in [23, Fig.8] and [2, Fig.7] are tested. Small random perturbations are added in the parameters of the evolution laws explaining the spatial variation of the PSFs to better represent the variability one can experience in a true acquisition device. Regarding the patch positions, we consider three cases, namely (i) non-overlapped \((T = 64)\), (ii) overlapped size \(8 \times 8 \) \((T = 81)\) and (iii) overlapped size \(32 \times 32 \) \((T = 225)\). The spiral order initialized in the image center is used for the model from [23, Fig.8] to better capture the radial symmetry of the kernels map. We set \( \sigma_n = 0.05 \) and \( \sigma_\theta, \sigma_r \) are chosen using a golden search to minimize the RMSE. Table 3 presents RMSE for BPF, BPF-BS, IS and MAP approaches for image Cells. Again, we clearly observe the improvement brought by our strategy. Moreover, as expected, increasing the overlapped size tends to improve the results quality, as more observations facilitate the inference task. Fig. 3 presents an example of results that illustrates the spatial regularization effect brought by the proposed state model, which contrasts with the non-regularized IS methods. We can also visually assess the advantage of using a parametric form for the kernel, when compared to the non-parametric MAP approach. The estimators derived by BPF-BS are the best among these four methods in all cases.

5. CONCLUSION

This paper addresses the estimation of PSF parameters for spatially varying blurs. We propose an original statistical modeling of the problem, accounting for the spatial dependency among neighboring kernels, and apply a sequential Bayesian inference technique in this context. Our results in different scenarios illustrate the good performance of the approach, including a useful uncertainty quantification. The novel approach opens many possibilities beyond this work. For instance, different noise distributions could be immediately used. Moreover, other state-space models, not necessarily Markovian, could be considered.
