Keywords: Na-ion battery, hard carbon, carbon nanofiber, microstructure

Abstract

Hard carbons are considered among the most promising anode materials for Na-ion batteries. Understanding their Na storage capabilities is of great importance for optimizing their structure and therefore achieving high performance. Herein carbon nanofibers (CNFs) were prepared by electrospinning and their microstructure, texture and surface functionality were tailored through carbonization at various temperatures ranging from 650 to 2800°C. Stepwise carbonization gradually removes the heteroatoms and increases the graphitization degree, enabling us to monitor the corresponding electrochemical performance for establishing a correlation between the CNFs characteristics and Na storage behavior in hard carbons. Outstandingly, we found for CNFs carbonized above 2000 °C, a single voltage Na uptake plateau at ~ 0.1V with a capacity of ~200 mAh/g. This specific performance may be nested in the higher degree of graphitization, lower active surface area (ASA) and different porous texture of the CNFs at such temperatures. We demonstrate via the assembly of a full CNF/Na₂Fe(SO₄)₃ cell the benefit of such CNFs electrode for enhancing the energy density of

full Na-ion cells. This finding sheds new insights in the quest for high performance carbon based anode materials.

Introduction

The revival of Na-ion batteries rely on the low cost and widely availability of sodium sources with the possibility of developing high performance, low cost electrode materials^[1,2]. High capacity P2-type $\text{Na}_{0.67}[\text{Fe}_{0.5}\text{Mn}_{0.5}]\text{O}_2$ ^[3] and high voltage polyanionic $\text{Na}_2\text{V}_2(\text{PO}_4)_2\text{F}_3$ ^[4] have been widely studied as potential cathodes, delivering comparable energy density with Li-ion batteries. Current anodes are based on the similar materials as that for Li-ion batteries, including carbon, alloys and metal oxides^[5]. However, Carbon have emerged as one of the most promising classes of materials in the searching of anodes, although widely used graphite cannot be blindly implemented with carbonate electrolyte^[6]. Only solvated Na ions could be intercalated into graphite when appropriate electrolyte, such as ether-based electrolyte, [xxx] is used. Therefore, other forms of carbon, such as hard carbon^[7] and graphene^[8], have been widely studied. A decent capacity of ~ 200 mAh/g could be obtained so that C-based Na-ion cells were assembled and tested^[9].

Hard carbon materials that contain randomly oriented graphene layers are the most studied candidate anodes. They are usually prepared by pyrolysis of organic and polymer precursors, such as glucose^[7], sugar^[10] and polypyrrole^[11], at around 1000 °C. Due to the presence of large amount of sp^3 structure in the precursor, parallel growth of graphene layers is somewhat inhibited, giving rise to plenty of defects. Like Li ion storage in carbons, Na ions can equally be stored in carbons via i) adsorption on the surface and defects, ii) nanopore filling and iii) intercalation between the graphene layers of large d-spacing. Although a number of studies have been conducted on the hard carbon anode, there are numerous discrepancies concerning the Na ion storage mechanisms as a diversity of both voltage profiles and capacities are reported. The charge/discharge curves of hard carbon normally consist of two regions: i) a

slope between 1.0-0.1 V and ii) one flat plateau at ~ 0.1 V. The first one has been explained by either Na insertion into nearly parallel graphene layers^[12] or binding of Na at vacancies^[13]. Equally, there is no consensus regarding the assignment of the flat plateau which is presented as due either to the Na intercalation between expanded graphene layers^[14] or to nanopore filling/nanoplatting^{[7] [12]}. Obviously these different assignments come from the variation in the microstructure/texture which depends on both the carbon precursor and thermal annealing processes. Moreover, the high capacity at above 1 V is also assigned to heteroatom doping^[15], hence calling for a careful examination on the effect of functional groups containing N and O atoms. Systematic studies on tailoring the microstructure and chemical composition of hard carbon are therefore required in order to establish a possible relationship between heteroatoms, microstructure, texture and electrochemical properties vs Na^+/Na^0 .

Carbon nanofibers (CNFs) prepared by electrospinning have been extensively studied in Li-ion batteries, serving as both anode materials and substrates for supporting metal oxides^[16,17]. Recent studies on neat CNFs and their hybrids with Sb suggests that they can also be employed in Na-ion batteries^[18,19]. Although CNFs have generally a lower density than graphite, a side advantage if that they can be made in flexible thin film forms to be used for wearable electronics^[20]. Because of the high carbon yield, low cost and easy spinnability, polyacrylonitrile (PAN) is considered among the most suitable polymer precursors to produce CNFs^[21].

Therefore, in this work self-sustained PAN derived CNF films by stepwise carbonization/graphitization were used for the understanding of Na ion storage mechanism. Gradually heating of PAN fibers between 650°C and 2800°C allowed to obtain several materials having distinct surface functionalities, textures, structures and reactivity as highlighted by systematic analysis using a large panel of techniques. Three domains of Na storage mechanism were identified based on the CNFs features induced by temperature interval

used for the carbonization/graphitization and the Na ion storage behavior. Importantly, a single voltage Na plateau at $\sim 0.1\text{V}$ with a capacity of $\sim 200\text{ mAh/g}$ is for the first time observed for high temperature treated CNFs ($> 2000\text{ }^{\circ}\text{C}$). Full cell based on such CNFs and $\text{Na}_2\text{Fe}_2(\text{SO}_4)_3$ was demonstrated to provide improved energy density for Na-ion full cells.

Results and Discussions

Scanning Electron Microscopy (SEM) images of PAN fibers in Figure S1a,b show a fine one-dimensional structure with fibers having diameters ranging from 100 to 300 nm and little amount of beads. This structure is well maintained during stabilization and carbonization, giving rise to uniform CNFs having slightly smaller average diameters (150 nm vs. 200 nm) and a more dense appearance than PAN fibers (Figure S1c,d). The carbon yield (i.e., the mass ratio of obtained CNFs to PAN) significantly decreases from 67% to 42% with increasing temperature between 650 and 950 $^{\circ}\text{C}$, respectively (Figure S2). No significant difference in the carbon yield is noticed for temperatures higher than 950 $^{\circ}\text{C}$. Several complementary analysis techniques were employed to determine the composition and surface functionalities of CNFs at different stages of carbonization/graphitization process. These functionalities, which are known to strongly modify the electronic and the wettability properties of the materials^[22] may play a key role in the interactions with the electrolyte and consequently impact the Na storage performances.

The elemental analysis and X-ray photoelectron spectroscopy (XPS) (**Figure 1a**) show an increase in carbon content and a decrease in the heteroatoms, i.e., nitrogen and oxygen amount with increasing temperature, especially between 650 and 950 $^{\circ}\text{C}$. In this region, it can be noticed as well that the oxygen content obtained from chemical analysis is higher than from the one deduced by XPS. Although this difference is nested in the fact that XPS is a surface technique probing solely $\sim 10\text{ nm}$ of carbon surface, as compared to elemental analysis which probes the whole sample, it indicates an oxygen gradient concentration between the core and

surface of the sample. Thus the need to increase the treatment temperature to fully carbonize PAN is evident, as confirmed by the homogenous O and N content for samples treated at $T > 1000^{\circ}\text{C}$.

Details about the types and evolution of N and O functional groups with the annealing temperature, as determined by deconvolution of the C1s, N1s and O1s XPS peaks are presented in Figure 1b and Figure S3. The main nitrogen groups are the pyridine, pyridine pyrolic and quaternary N while for O mainly carbonyl ($\text{C}=\text{O}$), anhydrides ($\text{O}=\text{C}-\text{O}$) and ether ($\text{C}-\text{OR}$) groups are observed. Both XPS and elemental analysis show that removal of N and O functional groups is the main reaction occurring below 1000°C (Figure 1a and Figure S3), explaining the observed decrease of carbon yield (Figure S2). The elimination of functional groups was *in-situ* monitored by temperature-programmed desorption coupled with mass spectrometry (TPD-MS). Figure 1c depicts the evolution of evolved gases during the TPD-MS experiment under vacuum for different thermal annealed CNFs. The basic and acidic oxygen functionalities are decomposed into CO and CO_2 , respectively^[23,24]. It can be seen that for all materials the CO quantity is predominant, indicative of the presence of basic rather than acidic groups, in good agreement with the XPS results. Concomitant with the CO_x evolution, the desorption of HCN was observed due to the decomposition of nitrogen functional groups (data not shown). The precise quantity cannot be determined since no calibration with such species was performed. Besides CO_x and HCN, water and H_2 is evolved. The water is usually physisorbed/chemisorbed on carbon or *in-situ* formed by decomposition of neighbor oxygen groups. The H_2 evolution is mainly attributed to C-H bond cleavage^[25] indicating carbonization of the fibers. As expected, all these groups are evolved in higher quantities at low temperature.

Once these groups removed, the materials were further subjected to oxygen chemisorption and TPD-MS analysis to determine the active surface area (ASA). We have previously shown for graphite materials that the ASA influences the formation of SEI, the

irreversible capacity loss in the first cycle and therefore the overall Li-ion battery performance. [25,26] However, studies about the active surface area determination for hard carbons and its impact on Na storage mechanism were never reported. Figure 1d shows the evolution of ASA for several CNFs heated at temperatures higher than 950°C (temperature where the most surface groups is removed). The ASA sharply decreases from 23 to 1.1 when increasing the annealing temperature between 950 and 1250°C. These values are very high indicating poorly organized and defective CNFs materials. For temperatures superior to 1250°C, the ASA slightly decreases with the temperature down to 0.36 for 2800°C treated material; a value comparable to what was obtained with some graphite materials [26]. To grasp further insights into the parameters (degree of graphitization, type of defects...) parameters, Transmission Electron Microscopy (TEM), X-ray diffraction (XRD) and Raman spectroscopy were performed.

Figure 1 (a) composition by elemental analysis (EA) and XPS; (b) deconvoluted evolution of functional groups of C1s XPS spectra with the carbonization temperature of CNF for CNF carbonized between 650 and 2200°C; (c) desorbed quantities of H₂, H₂O, CO and CO₂ gases from CNF surface during TPD-MS analysis and (d) the active surface areas.

TEM pictures CNFs treated below 1000°C (**Figure 2a-c**) show disordered structure without clear evidence for graphene layers, most likely due to the lack of sufficient energy to drive the growth of such graphitic structure. In contrast, ~10 nm islands of curved graphene layers with random orientation are observed for samples treated at above 1000°C (Figure 2c-e); somewhat similar to the "card house" model proposed by Dahn et al^[27]. These observations explain the high ASA value for the material treated at 950°C and its decrease for higher temperatures: lower the structural organization higher the ASA. For samples annealed at $T \geq$

2000°C (Figure 2f-h) the graphene domains tend to orient in the basal plane as deduced from TEM images which shows that they consists of packing of 3 to 20 parallel graphene layers. This structural rearrangement results in the creation of mesopores whose importance with respect to the capturing of Na^+ ion will be discussed latter. Such a growing and orientation trend of the graphene domains increases with increasing further the heating temperature to 2800°C. The graphitization improvement under high temperature annealing is also confirmed by selected area electron diffraction as shown in the inset of Fig.2 (a),(c), (f) and (h). The diffraction rings are clearly observed in CNF-2200 and CNF-2800, but not in CNF-650 and CNF-1250 due to their less ordered structure. Nevertheless, we are still remaining far away from a dull graphitization, the reason why PAN derivated carbon belongs to the hard carbon family.

Figure 2 TEM images of (a) CNF-650 (b) CNF-950 (c) CNF-1250 (d)(e) CNF-1550 (f)(g) CNF-2200 and (h)(i) CNF-2800. The insets of (a)(c)(f)(h) show the selected area electron diffraction of corresponding samples.

In parallel to microscopy, XRD patterns (**Figure 3a**) reveal the existence of a wide (002) peak for CNFs carbonized at below 1000 degree which is indicative of structural disordering in agreement with the microscopy. The intensity of (002) peak improves when the carbonization temperature increases, but it remains broad till up to 1550 °C. A further increase of carbonization temperature above 2000°C leads to a sharpening of the (002) graphitic that is reminiscent of an increase in the sample state of graphitization. To quantify these effects we further exploited the collected XRD patterns using the Bragg's law and Sherrer's formula. With increasing the carbonization temperature (Figure 3b) the d-spacing decreases by about ~5% to reach a value of 0.343 nm at 2800°C, which is close to that of graphite (0.335 nm), while the crystallite size increases from 0.4 at 650°C to about 6nm at 2800°C. This result may partly explain why similar ASA values are obtained for the CNFs as some graphite materials. In addition, the graphitization enhancement with temperature was also proven by Raman spectra (Figure S4), where a prominent G' band peak appears when the temperature reaches 2000°C. Nevertheless, the D band peak is still intense even after carbonization at 2800°C, indicating the presence of defects and/or pores^[28].

Figure 3 (a) XRD spectra and (b) derived d-spacing and crystalline size (L_c) as function of carbonization temperature

Insights on the textural features of CNFs were assessed by nitrogen and carbon dioxide adsorption. The nitrogen adsorption/desorption isotherms presented in **Figure 4a** exhibit a type II-shape for all CNFs materials specific to materials having low porosity. The BET surface area is similar for all materials ($\sim 20 \text{ m}^2/\text{g}$), no matter the carbonization temperature, while the total pore volume tends to increase for high temperature annealed CNFs (Table 1). For sake of completeness we also determined the textural properties by CO_2 adsorption. The CO_2 adsorption isotherms (Figure S5) show a significant decrease in the adsorbed volume with the increase of the temperature between 650 and 950°C. For higher temperatures (1100-2800°C) the adsorbed volume is similar between the materials. If we compare the specific surface area and the total pore volume of CO_2 with N_2 (Table 1) it can be seen that for CO_2 the values are about 5 to 10 times higher for low thermal treated CNFs (650-950°C). For higher temperatures, the CO_2 specific surface area becomes similar to the nitrogen one. This observation suggests

the presence of ultramicropores for CNFs treated bellow 950°C. Compared with N₂ it is well known that CO₂ is able to access better the narrow pores (ultramicropores) due to the enhanced diffusion, thus higher CO₂ may be adsorbed. It must be recall that these materials contains high amounts of nitrogen and oxygen functionalities, which may influence the CO₂ adsorption behaviour due to the presence of a quadrupole moment. However, this aspect remain still controversial in the literature.^[29,30] In addition, the DFT pore size distribution (Figure 4b) show different pore size depending on the annealing temperature. For low temperatures (650-950°C) only micropores with size of about 1.2 nm are seen, while for higher temperatures small mesopores (3.2 nm) are formed. The formation of mesopores for temperatures superior to 950°C is as well confirmed by BJH model (Figure S5a). We believe that the micropores to mesopore evolution of CNFs with temperature can be explained as follows. The micropores present at low temperature (650°C) most likely due to the poor stacking of C-C aromatic structures. The presence of functional groups are progressively disappear with increasing the carbonization temperature at the expense of graphene layers growth through which part of C atoms are expelled via the evolvment of CO_x and HCN to leave mesopores behind (as sustained TPD-MS and mass loss with the temperature). Moreover, the rotation of graphene layers with increasing temperature, as deduced from TEM measurements, could also in addition participate to the formation of mesopores.

Table 1 Textural properties of CNFs determined by N₂ and CO₂ adsorption.

Materials	CNF-650	CNF-800	CNF-950	CNF-1100	CNF-1250	CNF-2200	CNF-2800
SSA N₂ (m²/g)	25	18	12	24	20	21	20

Vt N₂ (cm³/g)	0.026	0.022	0.015	0.033	0.028	0.040	0.037
Vt CO₂ (cm³/g)	0.13	0.11	0.038	0.0058	0.0037	-	-

Figure 4 (a) N₂ adsorption-desorption isotherms (b) DFT pore size distribution of CNFs carbonized at various temperatures.

So overall, based on all these analysis techniques we can deduce that CNFs undergo during carbonization up to 2800 °C a three stages process enlisting subsequently i) the elimination of heteroatoms (650-950 °C) and ultramicropores; II) the growth of graphene domains (1000-2000 °C) and III) the graphitization (>2000 °C) with the formation of small mesopores. At this stage a legitimate question deals with the importance of such carbonization sequences on the electrochemical properties of the resulting CNFs. Thus, the CNF films were punched into disks for using as electrodes in coin cells to evaluate their Na storage performance. The results are presented in **Figure 5** by grouping the samples according to the three domains of temperatures defined above I, II, and III.

For stage I CNFs the voltage profiles show initially a pseudo plateau followed by a monotonous decrease of the voltage to 0 V with therefore a large irreversibility between the first discharge and first charge so that the total sustainable reversible capacity is limited 200 mAh/g. The high irreversible capacity can be ascribed to the disordered nature of the carbon as determined by XRD and TEM analysis. Note that 50 % of this charge capacity in CNF-650 is obtained at voltages greater than 1 V, due most likely to the high content of heteroatoms (17.9% N and 10.6% O) in the samples in agreement with a previous study which has reported

similar voltage profiles for N doped CNFs ^[31]. Moreover, the decrease of the high voltage charge capacity contribution with increasing temperature (from 650°C to 950°C see arrows Figure 5a) does not come as a surprise since we have shown by XPS and TPD that the heteroatoms are progressively eliminated as the temperature is increased. A short low plateau at around 0.1V pop-out in CNF-950, leading to the slightly higher capacity of CNF-950 than CNF-800 although the latter has higher capacity at above 1V. The capacity at around 0.1V is related to the presence of tiny graphene layers spotted by TEM measurements (Fig. 2a) with the corresponding Na storage mechanism explained as follows.

For CNFs pertaining to the stage II temperature domain (1100 – 1550), the voltage profile can be divided into two regions, i.e., sloping region between 1-0.1 V and a flat plateau region at ~ 0.1V that could remind alkali intercalation in graphite-type materials. Although Na interaction into graphite is not possible in carbonate electrolytes, it is worth mentioning here that recent studies have proposed that intercalation of Na⁺ in graphene domains showing large d-spacing^[14,32] to account for the low voltage plateau^[14]. This is in contrast with Dahn's early work in which the low voltage plateau is ascribed to nanopore filling^[12].

As an attempt to distinguish between these two possibilities, we electrochemically test CNFs treated at T > 2000°C which are characterized by a high degree of graphitization. The first discharge curves show a initial plateau corresponding to SEI formation and afterwards a long plateau showing a reversible capacity of ~200 mAh/g which maintain at 173 mAh/g after 50 cycles. Surprisingly, from the second cycle onwards, the two sloping and constant voltage regions present in stage II samples have merged into a single voltage plateau in stage III samples. It should be recalled that the materials prepared in this temperature interval present a high degree of graphitization, small mesopores and low active surface area (ASA < 0.5 m²/g), hence low reactivity with the electrolyte.

Figure 5 Voltage profiles (top), discharge capacity retention (middle) and schematic representation of Na ion storage mechanisms (bottom) in (a) Stage I, (b) Stage II and (c) Stage III CNFs.

To grasp further insight into any possible Na interaction, in-situ XRD measurements were conducted in a Swagelok type cell equipped with a beryllium window. While the cell being discharged to 0 V, XRD patterns were collected at times refereed as circles in the voltage trace. Note that the collected XRD shows a broad background due to the electrolyte/separator contribution centered near $2\theta = 20^\circ$ which overlaps with the peak pertaining to carbon centered at $2\theta = 25.5$. To prevent any experimental artifacts, such background was systematically subtracted and the obtained XRD collection shown in **Figure 6**. No shift of the (002) peak was observed when the cell discharged to 0V. A similar experiment was conducted on the same

sample vs. Li^+/Li and in contrast to Na storage, the intercalation of Li between graphene layers is clearly observed as deduced by the left shift of (002) peak position during discharging together with its return back to the initial position upon charging (Figure S6). This highlights a different alkali uptake mechanism between both alkalis. The constancy of the d-spacing for Na-uptake in CNFs fiber implies that the low voltage plateau cannot be attributed (assigned) to Na intercalation.

Of course one still argue about the feasibility of having Na plating since the long voltage Na uptake plateau is close to 0 V vs. Na/Na^+ . To eliminate this possibility the *in-situ* XRD cell was further discharged to below 0 V to purposely provoke Na plating. When the cell voltage approaches -0.015V, the voltage trace shows a “V” shape characteristic indicative of the Na nucleation-growth process as further confirmed by the *in-situ* collected XRD patterns which show the progressive emergence of a small peak near $2\theta = 29^\circ$ corresponding to Na metal (Figure 6 and Figure S7). From such experiments we can unambiguously conclude that the low voltage plateau is neither due to Na intercalation nor Na plating. Note therefore that the capacity of the low voltage plateau become the most prominent only for samples treated at above 1000 °C which contains greater amounts of mesopores, hence in good agreement with the nanopore filling model^[33]. The mesopores are partly removed when the temperature increases to above 2200 °C as a result of the further orientation of the graphene layers in the basal plane (Fig.2), which leads to the decrease in the capacity of CNF-2500 and CNF-2800.

A comparison between Stage II and Stage III CNFs shows that the sloping region almost disappears once the graphene sheets become parallels with smaller d-spacing. This implies that the sloping region is related to the Na storage in isolated or randomly oriented graphene layers. In-situ XRD does not show a clear shift of the (002) peak during discharging for stage II CNFs, probably due to adsorption of Na ions on the surface of graphene sheets instead of intercalation (Figure S8). It should be noted, however, the possibility of Na intercalation cannot be fully

excluded in stage II CNFs because of the broadness of (002) peak which renders unreliable the detection of minor shift positions. This is one of the reason why the Na storage mechanism in less ordered carbon treated under this temperature range remains controversial [xx], requiring further investigations among which Na NMR could be quite useful. A little amount of isolated graphene sheets is remained in stage III CNFs, giving rise to the small capacity between 0.1 and 1V.

So in light of the aforementioned results, the Na ion storage mechanism in CNFs enlists three different steps, depending upon their microstructure, composition and texture. They consist in i) the uptake of Na^+ by defect sites created by heteroatoms (*mainly by N as O will lead to higher potentials*), 2) the Na adsorption on disordered isolated graphene sheets resulting in a sloping region between 1V-0.1V and iii) in the mesopore filling that occurs at $\sim 0.1\text{V}$ (Figure 5).

Figure 6 X-ray diffraction pattern recorded in-situ on the first discharge of CNF-2200, the cell was discharged at a current density of 35 mA/g. The peak marked with * is due to the side reaction with the electrolyte.

For sake of comparison, the electrochemical behavior of all CNFs samples was investigated in Li-ion cells and only the most relevant voltage composition profiles, within the context of the paper, are reported in Figure S9. Stage 1 samples show both a large hysteresis

together with a sloping region alike what was found with sodium and this was explained using similar storage mechanisms^[34,35]. Turning to stages II and III, we note a decrease in the hysteresis, but neither of them show the onset of a well pronounced plateau at low voltage as observed for sodium, further confirming a different Li and Na uptake mechanisms at low voltage, despite the fact that these materials are alike in terms of microstructures, defects and morphologies.

Stage III CNFs that possess a single plateau at low voltage having a ~200 mAh/g capacity could be attractive anode materials for delivering a high output voltage when coupling with cathodes. For proof of concept, full Na-ion CNF/Na₂Fe₂(SO₄)₃ cells were assembled using as negative electrode CNFs samples treated at 1400°C and 2200°C (**Figure 7**). The voltage profile of Na₂Fe₂(SO₄)₃ that prepared according to the literature^[36] in half cell is shown in Figure S10. Both the cells deliver a stable capacity of ~ 70 mAh/g (based on the weight of Na₂Fe₂(SO₄)₃, suggesting electrospun CNFs could be potential anodes for Na-ion batteries. Efforts are ~~made~~ undertaken to prepare large badges at low cost; which ~~is~~ should not represent an unsurmountable task [xx]."

~~providing that efforts are made to prepare large badges at low cost; which is not an~~
~~unsurmountable task [xx].~~ The capacity of CNFs are normalized to compare the influence of CNF voltage profile on the full cell. It can be seen that without sloping region Na₂Fe₂(SO₄)₃/CNF-2200 cell has higher output voltage than Na₂Fe₂(SO₄)₃/CNF-1400, showing potential improvement in energy density. Furthermore, synthesis of mesoporous carbon has been well studied in carbon community, thereby opening a wide window on synthesis high capacity carbon anode material through optimizing the porous and graphitic structure.

Figure 7 Electrochemical performance of full cells using Na₂Fe₂(SO₄)₃ and CNFs as cathode and anode, respectively. The capacity of CNFs is normalized to compare their voltage profiles and influence in the full cell.

Conclusions

We have reported the preparation of CNFs from carbonization of electrospun PAN fibers and shown that their electrochemical performances towards Na strongly depend upon their characteristics induced by carbonization temperature. Using combined TEM, TPD-MS, XRD and adsorption techniques, we demonstrate that the materials present distinct textural, structural, and surface chemistry characteristics depending on the carbonization process. Low temperature made CNFs contain copious amounts of O and N heteroatoms, high disordered structure and high amounts of ultramicropores. Carbonization at $T > 1000^{\circ}\text{C}$ gradually remove the heteroatoms and increases the ordered structure as well as the mesoporous volume. We find for temperatures of above 2000°C the emergence of high density of graphite-type domains consisting of numerous pores surrounded by graphitic layers. Among the most pleasant result is the appearance of a low and single voltage plateau at $\sim 0.1\text{ V}$ which displays a reversible and sustained capacity close to 200 mAh/g . While such low single voltage plateau is common for

Li insertion in graphite, it is to our knowledge the first time that it has been observed for Na as well. We demonstrated here that this plateau is nested in the filling of the CNFs nanopores by Na^+ ions. Application-wise, we show the beneficial aspects of CNFs made by a scalable process, via the assembling of full $\text{CNF}/\text{Na}_2\text{Fe}_2(\text{SO}_4)_3$, which show better energy density. Obvious optimizations of this work range for means to i) design carbonaceous materials at lower temperatures for sustainable reasons while preserving similar performances, and ii) to eliminate their large irreversible capacities so that such electrodes could be used in Na-ion commercial cells. The above aspects are being explored to further exploit the right balance between porous and graphitic structure for elaborating electrochemically optimized carbons for the Na-ion technology.

Experimental Section

CNFs Preparation: CNF films are produced by electrospinning using PAN (Sigma, Mw of 150,000) as precursor. 6wt.% PAN was dissolved in N-dimethylformamide and was stretched into fiber shape under a high voltage of 18 kV. The feed rate of PAN solution was 3.0 ml/h using a needle of diameter 1.2mm. A PAN fiber film was peeled off from Al plate collector, and stabilized at 250 °C for 3h in a muffle furnace so as to achieve a cyclic structure and hence avoid the melting of PAN during high temperature treatment^[37]. It was then carbonized under Ar atmosphere for 1 h at various temperatures between 650 and 2800 °C. The duration of treatment for temperature higher than 2000 °C was reduced to 20 min due to the furnace manufacturing limitation. The as obtained samples are denoted as CNF- x , where x represents carbonization temperature.

Material Characterization: XRD of CNFs was conducted using a Bruker D8 diffractometer with a Cu $K\alpha$ radiation source. The morphologies was characterized by SEM (Philips, XL30) and TEM (JEOL 2010F). The material composition and surface chemistry

were evaluated by several complementary techniques. The global composition was determined with a Thermo Electron EA112 elemental analyser instrument. The CNFs surface functionality was assessed by XPS with a VG ESCALAB 250 spectrometer using an Al K α monochromatic source (15kV, 15mA) and a multi-detection analyzer, under 10⁻⁸ Pa residual pressure.

Bulk groups functionality of materials was analyzed by TPD-MS. The CNFs were heat-treated in vacuum up to 950°C and the evolved gases were monitored by a mass spectrometer priory calibrated using N₂, H₂, CO, CO₂ and H₂O. The total amount of each gas released was computed by time integration of the TPD curves. The ASA was determined by performing TPD-MS experiments on CNFs cleaned under vacuum at 950°C and subsequently exposed to di-oxygen chemisorption at 300°C. More details about the procedure can be found in our previous works [25,26].

The textural properties of the CNFs were determined from the study of the adsorption isotherms of N₂ at 77K and CO₂ at 273K using a Micromeritics ASAP 2020 instrument. Prior to the analysis the CNFs were pressed to reduce their volume and then out-gassed overnight under vacuum at 300°C. The BET surface area (S_{BET}) was calculated in the relative pressure range of 0.05-0.3 for N₂ adsorption. The total pore volume V_p was obtained from the amount of N₂ adsorbed at a relative pressure of 0.95 and 0.03 for N₂ and CO₂ adsorption, respectively. The pore size distribution was assessed by DFT model for slit pores more adapted for these materials^[38], but also by BJH adsorption for comparison reasons.

Electrochemical tests: CNF films were punched into a circle with diameter of 11mm and typical weight of 1mg. It was used directly as electrodes in 2032 coin cells, where a Na metal was used as counter electrode. 1M NaClO₄ in ethyl carbonate (EC)/dimethyl carbonate (DMC) (1:1 by volume) and glass fiber (Whatman, GF/D) were employed as the electrolyte and separator, respectively. The cells were cycled between 0-3V at a current density of 50 mA/g in galvanostatic model using VMP system (Biologic S.A., Claix, France), taking around

8h for one full cycle depending on the capacity.- Swagelok style cell with a beryllium window was fabricated for in-situ XRD measurements.

A correlation between the microstructure and Na-ion storage behavior in hard carbon materials is established. A single low voltage plateau is observed in the carbon materials annealed at above 2000°C. It is demonstrated via the assembly of a full cell the benefit of such single low voltage plateau for enhancing the energy density of Na-ion batteries.
