ABSTRACT

Rohmer, J.; Louisor, J.; Le Cozannet, G.; Naveau, P.; Thao, S.; and Bertin, X., 2020. Attribution of extreme wave height records along the North Atlantic coasts using hindcast data: feasibility and limitations. *In*: Malvárez, G. and Navas, F. (eds.), *Proceedings from the International Coastal Symposium (ICS) 2020* (Seville, Spain). *Journal of Coastal Research*, Special Issue No. 95, pp. 50-54. Coconut Creek (Florida), ISSN 0749-0208.

Extreme Event Attribution (EEA) aims at answering questions about how much climate change influenced the probability or intensity of a specific type of extreme meteo-oceanic event. Here, we focus on wave record breaking i.e. the occurrence of an extreme significant wave height (h_s) value that exceeds all past observations. The objective is to evaluate the probability changes related to climate change by estimating the fraction of attributable risk $far=1-p_0/p_1$, where p_0 and p_1 are probabilities of the wave record event in two different worlds: a counterfactual world without anthropogenic forcings i.e. a “world that might have been”, and the “world that is” so called factual world. To define these different worlds, we rely on a wave hindcast database, which provides very long time series (1900-2008) of h_s over the whole North Atlantic Ocean Basin (NAOB). We assume that the counterfactual world corresponds to the series of annual h_s maxima over the period 1900-1930, and that the factual world corresponds to the annual h_s maxima over the period 1978-2008. The extreme event attribution approach dedicated to record breakings was applied over NAOB, and we show large far values (>0.5) along the northern Canadian, Scottish and southwestern Norwegian coasts (over the latitudes 50° - 65° N). These results are, however, carefully discussed with respect to different uncertainty sources, namely the validity of the assumptions underlying the EEA, the statistical uncertainties, the use of hindcast data instead of global climate model’s results, and the limitations in the hindcast database setup.

KEYWORDS: *Climate Change, Extreme Event Attribution, Wave, Fraction of Attributable Risk, Uncertainties.*

INTRODUCTION

The task of attribution can be defined following Bindoff *et al.* (2013) as the process of evaluating the relative contributions of multiple causal factors to a change or event with an assignment of statistical confidence. In other words, event attribution aims at answering questions about how much climate change influenced the probability (or intensity) of a specific type of weather event. Different methods to detect and attribute a human influence in the change of likelihood of extreme events have been developed (see Stott *et al.* 2016 for a review) with applications to different types of natural phenomena like hurricane-induced heavy rainfall, *e.g.*, van Oldenborgh *et al.* (2017); heat waves: *e.g.*, Hauser *et al.* (2017), Otto *et al.* (2012), *etc.*

The present study is focused on a risk-based extreme event attribution (EEA) approach, which aims at evaluating the probability changes of an extreme event related to climate change. This approach is based on the estimate of the risk ratio $RR=p_1/p_0$,

where p_0 and p_1 are probabilities of the same event, but under two different situations: a “world that might have been” (a counterfactual world without anthropogenic forcings) and the “world that is” (a factual world). The fraction $far=1-1/RR$ then measures the proportion of the current risk that is attributable to past greenhouse gas emission (see *e.g.*, Stott *et al.* 2016). If far significantly differs from 0 (i.e. with high confidence), this means that factors / processes present in the factual world (and absent in the counterfactual world) have changed the probability of the considered event.

Different statistical methods and approaches have been developed for EEA (Naveau *et al.* 2019), and in the present study, we rely on the EEA method recently developed by Naveau *et al.* (2018) to deal with record breakings, *i.e.* the event of interest is the occurrence of an observation that exceeds all past observations. We focus on extreme sea states, characterized by high significant wave height (denoted h_s) and aims at estimating the far indicator regarding the record breaking for annual h_s over the North Atlantic ocean basin (denoted NAOB). A careful attention is paid to discuss the results with respect to different uncertainties, namely the validity of the assumptions underlying the EEA, the statistical uncertainties, the use of hindcast data instead of Global Climate model’s results, and the limitations related to the hindcast database setup.

METHODS

*Corresponding author: j.rohmer@brgm.fr

Data

The key ingredient of any EEA is the definition of a counterfactual world. There are different possible ways by making use of : (i) past historical observations; (ii) climate models in the historical period; (iii) climate models with pre-industrial runs; (iv) climate models where greenhouse gas emissions have been removed, etc. (see an exhaustive review by Jézéquel *et al.* 2018). For wave heights, the use of observations is hindered by the starting date, which is often incompatible with the counterfactual assumptions, whether for buoy data (whose spatial resolution can also be a limitation), or for satellite data (with starting date often in the 80s, see e.g., Young and Ribal (2019)) or for visual observations (like wave height derived from Voluntary Observing Ships, see e.g. Gulev and Grigorjeva 2004). Sea state characteristics are not directly computed by climate models, which can hardly be used as such for wave EEA contrary to other variable of interest like temperature (e.g., Otto *et al.* 2012). Therefore, we rely on the wave hindcast dataset by Bertin *et al.* (2013), which has the advantage of a very large temporal coverage (1900-2008) as well as a large spatial coverage over NAOB (Figure 1).

The numerical hindcast is based on a regional implementation of WaveWatch III spectral wave model (Tolman 2009), forced with 3-hourly wind fields originating from the 20CR reanalysis V2 (Compo *et al.* 2011). The data used in this study consist of 6-hourly time-series of significant wave heights hs over the North Atlantic Ocean (80°W–10°E; 0°N–80°N) at 1°×1° spatial resolution. From the hindcast dataset, we extracted the annual maximum values of hs over the whole basin. To represent the factual and counterfactual worlds, the time series at each spatial location of the model grid is divided into two parts: 1900–1930 and 1978–2008. Figure 1a,b provides the maxima for the counter- and the factual period, respectively. From a mere visual inspection, we can notice that changes in the spatial extent of the region where $hs > 10$ m appears to be larger in the factual period.

Extreme event attribution (EEA) approach

Full details on the EEA methods are available in (Naveau *et al.* 2018). We recall here the main assumptions.

Consider a time series $\mathbf{Y}=(Y_1, Y_2, \dots, Y_k)$ of annual data (that are assumed to be independently and identically distributed). The year r is considered a record if $Y_r > \max(Y_1, Y_2, \dots, Y_{r-1})$. Let us denote $\mathbf{Z}=(Z_1, Z_2, \dots, Z_k)$ and $\mathbf{X}=(X_1, X_2, \dots, X_k)$ the time-series of the variable of interest in the factual world and the counterfactual world respectively. The probability $p_{0,r}$ of having a record after a sequence of length $r-1$ in the counterfactual world is $1/r$. The probability $p_{1,r}$ is the probability that an a realization of Z_r in the factual world have been a record in the counterfactual world if $(r-1)$ values of X_r were already observed. It is assumed to be written as follows:

$$p_{1,r} = E(G(Z)^{r-1}) = E(\exp(-(r-1)W)) \quad (1)$$

where $E(\cdot)$ is the expectation, G is the cumulative distribution function (CDF) of $\mathbf{X}$ and W is random variable derived as follows:

$$W = -\log(G(Z)) \quad (2)$$

By assuming that W follows a exponential distribution of mean θ , the probability $p_{1,r}$ holds as follows:

$$p_{1,r} = \frac{1}{1+(r-1)\theta} \quad (3)$$

Figure 1. Spatial evolution of the maximum hs values over the North Atlantic Ocean Basin (domain boundaries are outlined by dashed blue lines) (a) for the counterfactual world defined over the time period 1900-1930; (b) for the factual world defined over the time period 1978-2008. The observation points Pt_1 and Pt_2 , where the analysis of Figures 2 and 3 are conducted, are outlined by blue dots.

Naveau *et al.* (2018) provide formulae to infer θ from the empirical estimator of G as well as the associated uncertainty (using the delta method). Based on $p_{1,r}$ and $p_{0,r}$, the *far* indicator can be evaluated to measure to which extent the occurrence probability of the record has changed between the counter- and the factual world.

RESULTS

The EEA procedure is first applied on the hs time series (Figure 2a, 3a), at two specific locations, namely at $Pt_1=(-1^\circ; 63^\circ)$ close to the North of the scottish coasts, and at $Pt_2=(-2^\circ; 50^\circ)$ at the entrance of the English channel (see locations in Figure 1).

Figure 2. (a) Time series of hs at the location at $Pt_1=(-1^\circ; 63^\circ)$. In blue: counterfactual data. In red: factual data; (b) Comparison between theoretical and empirical CDFs for the random variable W ; (c) Exponential QQ plot; (d) far evolution depending on the considered return period r . The shaded area represents the 90%-confidence-interval band for the estimated far .

Considering the first location Pt_1 , Figure 2b shows that the cumulative distribution function CDF of the transformed random variable W (eq. 2) is well modelled by an exponential function. This is also confirmed by examining the alignment of the dots in the QQ plot of Figure 2c. The validity of the assumption of the exponentiality for W is further supported by the test of Cox and Oates (1984), which yields a large p-value of $\sim 70\%$, i.e. superior to the significance threshold chosen here at 5%. This indicates that there is no reason to reject the exponential model. On this basis, the evolution of far depending on the choice of a particular return period r is computed (Figure 2d) together with the 90%-confidence-interval band. On this basis, we can deduce that $far(r)$ is significantly different from zero with a value reaching around 0.6 (for $r=31$ years). This value is associated with high confidence, because the lower bound of the 90%-confidence interval significantly exceeds zero.

Considering the second location Pt_2 , the same analysis is performed. Figure 3b,c support the assumption of the exponentiality of the transformed random variable W . This is also supported by the large p-value of $\sim 60\%$ for the test of Cox and Oates (1984). Figure 3d depicts the evolution of far

depending on the considered return period r together with the 90%-confidence-interval band. Here, we can deduce that $far(r)$ reaches around 0.5 (for $r=31$ years). Yet, contrary to Figure 2, the confidence in this result is lower, because the lower bound of the confidence interval is lower than zero while the upper bound is non-zero. This uncertainty in the estimates prevents us from drawing a firm conclusion on the attribution.

Figure 3. (a) Time series of hs at the location at $Pt_2=(-2^\circ; 50^\circ)$. In blue: counterfactual data. In red: factual data; (b) Comparison between theoretical and empirical CDFs for the random variable W ; (c) Exponential QQ plot; (d) far evolution depending on the considered return period r . The shaded area represents the 90%-confidence-interval band for the estimated far .

The analysis is conducted at all spatial locations of the NAOB. Figure 4 shows the far estimates for $r=31$ years. This indicates that the northern part of NAOB and the coasts of the northwestern part of Africa present significant far estimates superior to 50%. Interestingly, the wave height on the European Atlantic coasts (SW of France and NW of Spain, and Portugal) appear to be affected only moderately (far ranges from 0.25 to ~ 0.50). The far estimates over the eastern part of the US appear to be of low values 10%.

The results of Figure 4 should, however, be carefully discussed with respect to different uncertainties.

DISCUSSION

Assumptions of the EEA approach

First, Figure 4 is derived without analysing the key assumption of the EEA approach, namely the validity of the exponentiality of W . Figure 5 now shows the far estimates (for $r=31$ years) by restricting to the locations where the p-values of the test of Cox and Oates (1984) exceeds the significance threshold of 5%. This clearly indicates that the exponentiality underlying the EEA approach is only valid in the northern part

of NAOB, in the northeastern part of South America and over the coasts of the northwestern part of Africa.

Figure 4. *far* evolution (for the return period $r=31$ years) over the North Atlantic Ocean.

Statistical uncertainties

As illustrated in Figure 3d, a non-zero *far* value does not necessarily mean high confidence in the estimate, because the lower bound of the confidence interval may fall below zero. To account for this problem, we update the results of Figure 5 by selecting only the locations where the lower bound of the 90%-confidence interval exceeds zero. Figure 6 shows that a large majority of the selected regions of Figure 5 have been filtered out, and more particularly the European Atlantic coasts where the *far* estimates were only of moderate values (over the range 25-50%).

Figure 6 shows that only the waves in the vicinity of the northern Canadian, Scottish and southwestern Norwegian coasts (over the latitudes $\sim 50^\circ$ - 65° N), as well as the Western Sahara, appear to present significant *far* estimates with high confidence.

The analysis was re-conducted by considering two alternative return periods, namely $r=11$ and 41 years, and the conclusions were similar (though we noted some slight changes in the spatial extent of the red coloured envelope in Figure 6).

Use of hindcast data

The findings of Figure 6, though robust regarding the assumptions of the considered EEA approach (as well as the statistical uncertainties), should be carefully analysed by keeping mind that the results are based on the use of hindcast data by Bertin *et al.* (2013).

First, the use of this type of data raises the question of the uncertainties related to the numerical model. Due to computational time and data storage limitations, Bertin *et al.* (2013) restricted the analysis on the ensemble-mean of the 20th

century reanalysis to force their hindcast. This could question the accuracy of wave predictions for the early part of the 20th compared to the atmospheric reanalyse that best represents extreme waves, particularly for high percentiles. Yet, Fortunato *et al.* (2017) showed that, in the NE Atlantic Ocean, this wave hindcast had satisfactory root mean squared discrepancies on *hs* ranging from 16 to 24%, without any particular bias for high percentiles. Such values provide a similar accuracy compared to wave hindcast forced with the popular NCEP reanalysis (e.g. Dodet *et al.* 2010). This brings additional elements for confidence in the results of Figure 6. The influence of boundary conditions of the numerical model should however be highlighted for regions below latitude 20° N, which might influence the *far* estimates for Gulf of Guinea: the results are here considered of low confidence.

Second, the results are presumably strongly dependent on how the counterfactual world is defined. Here, it is based on the 1900-1930 time period of the hindcast dataset. In this sense, the results do not give a complete account of the effects of climate change, because the world of the past (i.e. before 1930) might already have been affected by anthropogenic emissions. A significant non-zero estimate in our study only means that processes / factors acting in the factual worlds (here 1978-2008) have led to changes of the probability of the breaking records (w.r.t. the counterfactual world 1900-1930).

Figure 5. Update of Figure 4 by only considering the spatial locations where the p-value of the test by Cox and Oates (1984) is larger than 5%.

CONCLUSIONS

The present study has focused on EEA for wave record breaking i.e. the occurrence of an extreme *hs* value that exceeds all past observations over the whole North Atlantic Ocean Basin (NAOB). The estimates of the fraction of attributable risk *far* together with the analysis of the different sources of uncertainties (EEA assumptions, statistical, and use of hindcast

data) indicate that the northern part of NOAB present significant *far* estimates superior to 50% (with high confidence), more specifically along the northern Canadian, Scottish and southwestern Norwegian coasts (over the latitudes 50°-65°N). These findings should be considered evidence that the processes / factors acting in the factual worlds (here 1978-2008) have led to changes of the probability of the *hs* breaking records (w.r.t. the counterfactual world 1900-1930). This finding brings an additional element, which is consistent (especially in the northern part of NOAB) with the conclusions by Young and Ribal (2019), who highlighted the increase in high-percentile *hs* over the period 1985-2018 using satellite observations.

Yet, the present study tells nothing about the physical processes that have led to such changes. A complementary analysis should focus on the link between climate ensemble runs and high-resolution ocean models to derive *hs* data where the effect of greenhouse gas emissions have been removed, but with the need to address the difficulties in the setup of counterfactual runs (see discussion by Naveau *et al.* 2019: Sect.3.2). In this view, initiatives like Morim *et al.* (2019), Reguero *et al.* (2019) and Mentaschi *et al.* (2017) should thus be intensified and properly combined with ensemble runs in the future.

Figure 6. Update of Figure 5 by both considering locations where the p-value of the test by Cox and Oates (1984) is larger than 5% and where the lower bound of the 90%-confidence interval exceeds zero.
