Abstract

Monohydrated and dihydrated calcium oxalate have been widely studied in the literature because of their role in urolithiasis, a mammal pathology responsible for the formation of stones in the kidney. It is clear that the physicochemical environment plays a crucial role in the crystal growth and the resulting morphologies of calcium oxalates. To study these processes, reliable models for the calcium oxalate's faces, exposed to water and potential additives, are needed. Here, we have used a total surface energy minimization approach to predict the crystal morphology of the calcium oxalate monohydrate and dihydrate phases. Surface energies were calculated at density functional theory level, taking into account surface relaxation and the effect of solvation. An excellent agreement was found between theoretically predicted morphologies and their experimental counterparts obtained by SEM, clearly demonstrating the importance of the inclusion of water in the model for the prediction of morphologies.

Introduction

Calcium oxalate polyhydrates are ionic crystals present in minerals and living organisms. They are, for example, found in most plant families under the name raphides,¹ where they are associated with diverse functions such as protection and structure.² Aside from their role in plant biology, calcium oxalates have also been extensively studied because of their role in urolithiasis. This pathology originates from the formation of stones in the urinary system, called kidney stones.^{3,4} The main constituents of kidney stones are now established and correspond to a limited number of well-defined crystalline phases: calcium oxalates (with different hydration rates), ammonium, calcium and magnesium phosphates and uric acid. In recent decades, calcium oxalate-based stones are the most frequently observed in Europe and North America (> 70% of all samples analyzed).^{3,4}

From a crystallographic point of view, the calcium oxalate family is classified according to its hydration rate: anhydrous calcium oxalate (ACO), whewellite ($\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$; COM), weddellite ($\text{CaC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$; COD) and caoxite ($\text{CaC}_2\text{O}_4 \cdot 3\text{H}_2\text{O}$; COT), while an amorphous phase has also been described in nanoparticles.⁵ In this study we focus on COM and COD as they are the two phases observed in kidney stones.^{4,6} Previously, the COM structure has been resolved by X-Ray and neutron diffraction,⁷⁻¹² suggesting two polymorphs: a first structure stable in the range 318K - 425K and a second in the range 293K - 318K. As kidney stones are formed at physiological temperature (≈ 310 K), only the second structure was considered in this work. It is monoclinic and belongs to the space group $P2_1/c$. The COD structure was also previously resolved by X-ray diffraction and is a tetragonal structure belonging to the space group $I4/m$.^{9,13,14}

COM has been observed by Scanning Electron Microscopy (SEM) in several *in vitro* syntheses in aqueous medium.¹⁵⁻¹⁸ Four faces came out as predominant from these studies: (010), (100), (021) and $(12\bar{1})$.^{9,16} The (010) and (100) faces are always observed, while either the (021) or $(12\bar{1})$ face is always present as well, sometimes both of them. The corresponding morphologies are presented in Table 1, together with the conditions leading to their appearance and corresponding references. As mentioned before, COM morphologies have been observed in kidney stones where they present morphologies similar to those presented in Table 1a and 1b.^{12,19} This is caused by the (010), (021) and $(12\bar{1})$ faces being less expressed, giving the

crystals a flat aspect, while they are stacked on the (100) face with proteins between them.¹⁹ Compared to the synthetic and kidney stone whewellite, mineral whewellite crystals exhibit a wider diversity in morphology.⁷ The (100), (010), (021) and $(12\bar{1})$ faces still show a strong occurrence, but the (001) face becomes the most exposed face in minerals. A large variety of other faces is observed more rarely in few crystals: (140), $(13\bar{1})$, $(12\bar{3})$, $(14\bar{1})$, (161), (140), (011), $(16\bar{1})$, $(15\bar{1})$, (013), (121), (112) and (031).

MORPHOLOGY
	A)	B)	C)
EXPERIMENTAL CONDITIONS	Synthesis in water, equimolar, T_{amb}	Synthesis in water, $T=37^{\circ}\text{C}$	Synthesis in U tubes filled with silica gel, equimolar, T_{amb}
REFERENCE	Chen <i>et al.</i> ²⁰	Millan ¹⁶	Franchini-Angela <i>et al.</i> ^{17,18}

The Hartman-Perdok (HP) theory²¹, the Bravais-Friedel-Donnay-Harker (BFDH) law²², the Ising Model²³ and the attachment energy method²⁴ have been used by Millan¹⁶ to predict COM morphology. According to the HP theory, only F faces (faces with a PBC in two dimensions) are exposed as they grow slower because they need to form strong bonds in two dimensions. According to BFDH model and the Ising model, (100), (001), (021), $(12\bar{1})$ and $(10\bar{2})$ faces are predicted in COM, while the attachment theory predicts the same faces, except for the $(10\bar{2})$ face. Tommasso *et al.*²⁵ have predicted COM morphology in a force field study and found a stabilization of the (100) face due to a solvation effect (pure water). Such a stabilization is not observed on the (001) face, possibly explaining why the (001) face is not observed in aqueous conditions experimentally.

Except for the last study, the main difference between theory and experiment originates from the (001) face which is always predicted theoretically, but never observed in syntheses nor in kidney stones. This may be due to the growth kinetics. Indeed, Milan¹⁶ observed that faces appeared in a defined order: first (100), then (010) and later (021) and $(12\bar{1})$. Furthermore, the (001) face is prevalent in minerals^{7,16} suggesting that this face may take more time to appear.

COD morphologies have also been reported in many *in vitro studies* and are shown in Table 2, together with the experimental conditions in which they occur and the appropriate references. As shown in Table 2a and 2c, COD crystals often have the form of a bipyramid dominated by (101) faces. Under certain conditions, the (010) face is intercalated between the two pyramids formed by the (101) faces as shown in Table 2b.^{20,26,27,28} Although COD is less observed in kidney stones than COM, it is found in a bipyramid morphology with the (101) face dominating as are the COD crystals found in marine sediments.^{29,30,31} As COM, COD morphologies have been predicted in the literature by HP theory, the BFDH law and the attachment energy method.³¹ HP analysis predicts the existence of five F-type faces: (110), (101), (010), (121) and (211), while from attachment energy analysis, only three faces are expressed: (101), (010) and (110). The difference between experiment and theory is evident: the (110) face is not found experimentally, while the (010) faces was shown above to depend on the presence of additional molecules for stabilization.

The scope of this contribution is to develop a theoretical approach able to predict the calcium oxalate growth in the presence of water with the aim of closing the gap between theoretical and experimental methods. The morphology prediction methods described above have strong limitations as they do not take into account possible rearrangements of ions present on the surface of the crystal. Furthermore, they do not explicitly take into account the effect of the solvent. These two contributions will affect the stabilization of particular faces and thus have an impact on the crystal morphology. To take into account these external factors explicitly, we have used total surface energy minimization in order to predict COM and COD morphologies, corresponding to the lowest total surface energy. Surface energies were calculated at a DFT

level in the presence, or absence, of a solvation layer above the surfaces and with geometric relaxation. The development of such a model, will allow the subsequent study of the interaction between solvated COM/COD and additives at an atomic level with the aim of designing drugs that inhibit crystal growth.

Methods

Bulk structures of COM and COD were obtained from Daudon *et al.*¹² (neutron diffraction) and Tazzoli *et al.*⁹ (X-ray diffraction), respectively. Calcium oxalate surfaces were built by adding a vacuum of 10 Å in the bulk unit cell, along the low Miller indices (see Figure 1). 11 surface models, with different miller indices, were built for COM and 11 for COD by cutting along the bulk along different angles. The COM and COD surfaces are composed of 160 and 226 atoms, respectively.

Figure 1: COM (100) surface construction from COM bulk. Initial data from Daudon *et al.*¹²

All geometry optimizations were carried out with the freely available DFT package CP2K/quickstep,³² based on the hybrid Gaussian and plane wave method³³ using the generalized gradient approximation Perdew-Burke-Ernzerhof (PBE) + D3 functional.³⁴ BLYP-D3³⁵ and OptPBE-vdW³⁶ functionals were tested in addition in order to compare surface energies calculations. The D3 Grimme method was used to account for the dispersion forces in the oxalate ions³⁷. Analytic Goedecker–Teter–Hutter pseudopotentials³⁸, a DZVP level basis set, and a density cutoff of 300 Ry were used.

Water molecules were added to fill the vacuum present in each surface model super cell with the *solvate* command of the GROMACS simulation package (v 5.1.2)³⁹ with an average density of 1 kg.L⁻¹. The Gromos force field 54a7⁴⁰ was used to describe interactions between oxalate and calcium ions and water molecules, while the SPC/E model⁴¹ was chosen for the latter. Calcium and oxalate positions were frozen using P-LINCS algorithm⁴² and a 500 ps simulation was performed to equilibrate the water molecules in the canonical ensemble (NVT) with a Nosé-Hoover thermostat to ensure thermal stability.^{43,44} The particle Mesh Ewald (PME) method was used to optimize calculation of long-range electrostatic interactions^{45,46} with a grid spacing of 0.12 nm and an interpolation of 4. A real space cutoff of 0.5 nm was used, and the Lennard-Jones interactions were truncated at the same distance. For reasons of calculation costs, only the first two layers of solvation were kept for performing the geometry optimization of the hydrated surfaces at the DFT level. Indeed, one geometry optimization could take up to 48 hours of calculation on 128 cores, on the GENCI supercomputer, while a geometry optimization had to be performed for all “dry” and hydrated surface models, as well as for the bulk models. This led to 46 geometry optimizations in total.

The surface energy γ_{vacuum} of dry surfaces was calculated as:

$$\gamma_{vacuum} = \frac{E_{surface} - E_{bulk}}{2A} \quad (1)$$

with A the surface area and $E_{surface}$ and E_{bulk} the potential energies of the surface and the bulk models, respectively. Hydrated surface energies were calculated as:

$$\gamma_{H_2O} = \frac{E_{surface,H_2O} - E_{bulk} - N \cdot E_{H_2O}}{2A} \quad (2)$$

whereby N corresponds to the number of water molecules in the solvation layers. $E_{surface,H_2O}$ is the potential energy of the solvated surface and E_{H_2O} is the energy of one water molecule as obtained from an NVT Born Oppenheimer Molecular Dynamics simulation (BOMD) of 10 ps followed by a geometry optimization of 93 water molecules in a 10×10×10 Å³ box with PBE-D3 functional.

Crystal morphology predictions were made by means of Wulff diagrams and using either surface or hydrated surface energies. The predictions are based on the Gibbs hypothesis⁴⁷ that the equilibrium shape of a crystal is the one minimizing the total surface energy of the crystal,

$$\Delta G = \sum_j \gamma_j A_j \quad (3)$$

with γ_j the surface energy of a specific face, and A_j the area of the face. ΔG then represents the difference in free energy between ions/molecules in a real crystal (with surfaces) and ions in an infinite crystal. Additionally, according to Gibbs⁴⁸, the length of the vector h_j normal to the face and drawn between the center of the crystal and the face, is proportional to the surface energy:

$$h_j = k \cdot \gamma_j \quad (4)$$

Equations 3 and 4 lead to the Wulff-Gibbs theorem which is applied here as implemented in the software developed by Zucker *et al.*⁴⁹ specifically for that purpose.

Larger models were built from the DFT relaxed surface models in order to investigate the interface between predominant COM/COD surfaces and bulk water by using GROMOS force field 54a7.⁴⁰ Indeed, the surface area was greatly increased by extension of the simulation box in two dimensions, parallel to the surface. These corresponding models have a surface 40 times larger than the DFT models and are composed of about 6000 atoms. Surface splitting was also increased from 10 to 50 Å. After addition of water molecules (to completely fill the vacuum), the simulation box contained around 50000 atoms. Water density profiles were calculated from 1 ns NVT simulations, while COM and COD atoms were constrained in the DFT equilibrium state.

Results and discussion

The COM case

Table 3 shows the resulting surface energies for surfaces in vacuum, compared to the corresponding energies upon addition of a bilayer of water. Using the surface energies in vacuum only the (010), (102) and (100) faces show up in the morphology prediction as shown

in Figure 2, which contradicts experimental observations. Specifically, the emergence of the (100) face in the morphology prediction may be surprising as it is less stable than other surfaces not present in the prediction. This highlights the importance of the crystal shape in the Wulff prediction as an unexpected face may be preferred over others if the resulting total surface energy is smaller. Especially, the none-appearance of the $(12\bar{1})$ face is striking as this is the second most stable surface in vacuum and was also reported in the oxalate crystal morphology literature.²⁵ Another surprising observation may be the appearance of the (100) face - which is also observed experimentally - as its surface energy is high. However, the Wulff predictions - and in fact natural processes alike - look for the most stable crystal shape and not for a simple combination of the most stable faces. This means that less stable faces may be preferred over others if this reduces the total surface energy of the crystal.

Table 3 : Surface Energies of Calcium Oxalate monohydrate (COM) in vacuum and with a bilayer of water.

face	γ_{vacuum} (J.M ⁻²)	γ_{H_2O} (J.M ⁻²)
(12 $\bar{1}$)	0.50	0.33
(021)	0.62	0.39
(010)	0.28	0.39
(001)	0.63	0.42
(011)	0.76	0.46
(102)	0.52	0.51
(120)	0.55	0.51
(012)	0.65	0.59
(100)	0.65	0.68
(101)	1.19	0.91
(110)	0.58	1.04

Figure 2: Morphology prediction of COM crystal in vacuum and based on γ_{vacuum} values in Table 3.

As suggested in the introduction, addition of a bilayer of water on the surfaces has a great impact on the surface energies. Indeed, the $(12\bar{1})$ and (021) faces are strongly stabilized (by -0.17 J.m^{-2} and -0.23 J.m^{-2} , respectively), whereas the (010) face is slightly destabilized ($+0.11 \text{ J.m}^{-2}$). As shown in Figure 3 (in comparison with Figure 3), the solvation effect strongly affects the morphology, mainly due to the emergence of the $(12\bar{1})$ face.

Figure 3: Morphology prediction of COM crystal with water molecules (bilayer), based on $\gamma_{\text{H}_2\text{O}}$ values in Table 3.

This morphology corresponds well to the Wulff prediction obtained with a force field by Tommaso *et al.*²⁵ Nevertheless, a disagreement with experimental data remains as the (001) face is not observed in synthesized COM. As suggested by Milan¹⁶, the (001) face is not observed in experimental data due to kinetic effects and, as can be seen in Figure 4a, removing the (001) face from the Wulff prediction leads to a more satisfactory morphology. Still, when compared to experimental data (Table 1a and b), the presence of the (010) surface remains underestimated. As shown in Figure 4b, slightly decreasing the (010) surface energy (-0.1 J.m^{-2}) leads to a better prediction of the (010) surface exposure. Unfortunately, the software by Zucker *et al.*⁴⁹ was not able to further increase the (010) face area in this way. It is important to note that the hydrated surface energies of the $(12\bar{1})$, (010) and (021) faces are very close to each other (0.33 , 0.39 and 0.39 J.m^{-2} , respectively), falling within the error window of used methods. The expression of these faces in crystals are therefore expected to be very sensitive to external factors such as temperature, additives, solvent and so on. Indeed, as can be seen in Figure 5, a slight decrease of (010) and (021) surface energies (-0.03 J.m^{-2}) causes the emergence of the (021) surface in the prediction leading to a close resemblance to the morphology found by Franchini-Angela *et al.*^{17,18} and with one of the mineral crystals in

Erreur ! Source du renvoi introuvable.. As a summary, all relevant COM faces are shown in figure 7.

Figure 4 : a) Morphology prediction of COM crystal with the water molecules, without (001) face. b) same but with a surface energy correction of -0.1 J.m^{-2} on the (010) face.

Figure 5 : Morphology prediction of COM crystal with water molecules, without (001) face and with energy corrections: -0.03 J.m^{-2} for (021) and (010) surface energies.

Figure 6: predominant COM faces

Next, the behavior of water over the COM surfaces was investigated by means of force field molecular dynamics simulations. Figure 7 represents the mean density profile of three entities: calcium ions, oxalate ions and water molecules, whereby the density of the water molecules coming from the COM structure (structural water) is left out. As said before, COM surface energies are strongly influenced by the presence of water which has an impact on the crystal shape: the (021), (12 $\bar{1}$) and (001) faces can be defined as hydrophilic ($\gamma_{\text{hydrated}} - \gamma_{\text{vacuum}} < 0$) while the (010) and (100) faces can be defined as hydrophobic ($\gamma_{\text{hydrated}} - \gamma_{\text{vacuum}} > 0$). This distinction can be perceived from the density profiles as in hydrophilic faces, water molecules are able to penetrate the surface in order to stabilize some under-coordinated ions leading to the appearance of water density peaks at in between the Ca²⁺ and oxalate ions density peaks. These particular H₂O peaks are labeled with black arrows in Figure 7 and are only present in the hydrophilic faces.

Figure 7: Density profile of water for COM (100), (010), (001) and (021) faces. Black arrows correspond to water molecules inside COM structure. Z is the coordinate orthogonal to COM surface.

The corresponding solvation layers are shown in Figure 8. For the hydrophilic surfaces, (001), (021) and (121) faces, water molecules (labeled with black arrows) are clearly found to position themselves inside the COM structure. Because of the cutting of the bulk structure to obtain the respective surfaces, crystallographic sites where structural water was positioned in the bulk, are left empty at the surface. The water molecules from the solvated model can fill these holes and stabilize the surface, lowering its surface energy. For the (100) and the (010) faces there are no holes in the structure, explaining why these faces are not stabilized by the use of a solvation

model. By consequence, in order to correctly describe, at the very least, the hydrophilic COM surfaces and obtain their respective surface energies a solvation model is needed.

Figure 8: water molecules (red and white) interacting with COM (100), (010), (001), (021) and (121) faces (blue : crystallographic water, yellow : Ca²⁺, green and red : oxalate). Black arrows corresponds to water molecules "inside" a given face.

The COD case

COD surface energies are reported in Table 4. The (101), (110), (010) and (011) faces are the most stable in vacuum as their surface energies are (almost) equal to each other and lower than all other calculated surfaces. These results lead to a rather correct morphology prediction (see Figure 9) in overall agreement with the theoretical morphology obtained with the attachment energies method.³¹ It is, however, in contrast with experimental observations where these four surfaces are energetically distinct.

Table 4 : Surface energies of COD in vacuum and with a bilayer of water molecules. Surface energies in J.m⁻².

face	γ_{vacuum}	γ_{H_2O}
(101)	0.29	0.24
(110)	0.29	0.28
(010)	0.29	0.35
(021)	0.46	0.39
(001)	0.47	0.41
(012)	0.42	0.42
(111)	0.59	0.42
(120)	0.41	0.42
(112)	0.46	0.44
(011)	0.30	0.46
(121)	0.48	0.46

Adding a bilayer of water molecules changes the surface energies, leading to more realistic results. Indeed, solvation leads to a slight stabilization of the (101) face and a slight destabilization of the (010) face causing the disappearance of the (010) face in the morphology prediction (See Figure 10). This result is coherent with COD syntheses observations where the (010) face is observed only in the presence of specific additives (see Table 2b).

Figure 9: Morphology prediction of COD in vacuum and based on γ_{vacuum} values in Table 4.

Figure 10 : Morphology prediction of hydrated COD and based on γ_{H_2O} values in Table 4.

However, this prediction is still not in full agreement with experimental data (see Table 2a and Table 2c) where the (101) face is the only exposed face. Adding an energy correction of $+0.2 \text{ J.m}^{-2}$ to the (110) face is necessary in order to obtain the morphology described in Figure 11, in close agreement with experimental observations. This energy is non-negligible suggesting that the COD crystal may not adopt the most stable morphology. Indeed, the (110) face is expected to be absent because of kinetics. The three relevant COD faces are presented in Figure 12.

Figure 11: Morphology prediction of hydrated COD with a surface energy correction of $+0.2 \text{ J.m}^{-2}$ on (110) face.

Figure 12: predominant COD faces.

The molecular dynamics simulations show that, similar to the hydrophilic COM surfaces, water molecules penetrate inside the (101) face structure (black arrow in Figure 13 and Figure 14) to stabilize the surface. This solvation effect is not observed for the (010) face which may explain why the face is not observed in syntheses and needs specific conditions to be expressed (*ie* additional molecules). Finally, a density peak was also found inside the structure of the (110) face (*cf* Figure 13) but no particular stabilization was observed.

Figure 13: Density profile of water for COD 010,101 and 110 surfaces. Black arrows corresponds to water molecules inside COM structure.

(101)

Figure 14: water molecules (red and white) filling empty water crystallographic sites at (101) interface (blue: crystallographic water, yellow: Ca^{2+} , green and red: oxalate). Black arrows corresponds to water molecules inside COM structure.

Conclusion

The aim of this contribution is to develop a theoretical approach to predict the growth inhibition potential of selected molecules on calcium oxalate in a drug design perspective. Reliable models for COM and COD exposed faces, in agreement with experimental observations, were thus obtained by means of *ab initio* total crystal surface energy minimization. It was found that a solvation model is crucial in order to obtain accurate surface energies and resulting morphologies. For most structures a very good agreement with experiment was obtained, while for some others the competition between thermodynamics and kinetics in the formation mechanism needs further investigation. In particular, the COM (001) face and the COD (110) face were predicted by our calculation while they are not observed experimentally. Removing those faces from the prediction was essential to obtain a morphology prediction in agreement with experiment. It is therefore clear that COM and COD crystals may not adopt the most thermodynamically stable morphology and are subject to kinetic effects.

TOC

Synopsis

Reliable models for COM and COD exposed faces, in agreement with experimental observations, were obtained by means of *ab initio* total crystal surface energy minimization. It was found that a solvation model is crucial in order to obtain accurate surface energies and resulting morphologies.
