KEYWORDS

Thermoset, eugenol, disulfide exchange, dynamic crosslink, self-healing, reshaping, recycling.

ABSTRACT Permanently crosslinked polymer networks, such as fully cured thermosets derived from fossil-based epoxies, cannot be reuse after damage and/or recycled since they cannot be reprocessed by heating or solubilization as non-crosslinked thermoplastics. As a result, they are not really sustainable materials, generating non-renewable resources consumption, CO₂ emissions and plastic pollution. Herein we employed a strategy to tackle the lack of sustainability in conventional thermosets by the development of a promising partially biobased epoxy for numerous applications, integrating a covalent adaptable network using associative dynamic chemistry and catalyst free mechanism. This strategy is based in two sustainable

approaches. First, vegetal biomass has been used as a renewable resource for the synthesis of epoxy systems from epoxidized eugenol oil. Then, the crosslinking reaction with an diamine integrating disulfide bonds to attain a thermally induced reorganizable eugenol-derived epoxy network in a dynamic way by disulfide metathesis reaction. The viscoelastic behavior characterization of eugenol-derived epoxy network displays a fast macroscopic flow with a stress relaxation time of 37 s at 230 °C, suggesting an interesting melt-reprocessability of this network at high temperatures in short times. Moreover, this strategy has a strong potential for the progress of sustainable plastic applications as yield a synthetic procedure to develop stiff thermosets (storage modulus of around 1 GPa at glassy state) with high renewable carbon contents (around 70 wt%), enhanced thermal properties (T_g of around 190°C) and additional properties such as promising reshaping, repairing and recycling capability.

Introduction

Nowadays, the entire value chain associated to polymers, in particular thermosetting polymers, is facing a rough scrutiny for its negative impacts in the economy and the environment. The global commitment to tackle these negative impacts involve that all plastic must be reused and/or recycled. Therefore, an efficient physical reprocessing strategy is necessary in order to stop the waste disposal into the environment, the consumption of non-renewable resources and CO₂ emissions. As a result, contribute achieving the EU Product Policy Framework of the Circular Economy targets.

Compared with non-crosslinked thermoplastics, thermosetting polymers present a large range of engineered advantages. Thermosetting polymers are nowadays widely used as adhesives, electrical castings, flooring and paving applications as well as matrices for structural performing

composites and foams. They globally represent 15–20% of plastics manufacture [1]. Among them, epoxy resins are of great economic importance as they represent around 70% of thermosets global market without including polyurethanes [2]. The development of more sustainable thermosetting epoxy materials with an improved LCA is a strong challenge nowadays. Then, to improve the environmental impact from cradle to grave, the properties and the behavior of this type of materials, two main ways can be underway and coupled (i) Developing more sustainable approaches during the synthesis (ii) Developing materials with an improved ends of life, in order that they can be reshaped, repaired or recycled after usage or damage.

For instance, dynamic covalent networks [3, 4] such as vitrimers [5-14] have been recently established as an innovative and new class of polymer that are characterized by a crosslinked network that when it is heated at a certain temperature it can flow without depolymerization. This behavior is due to the occurrence of thermally activated crosslink exchange reactions of the network in an associative manner without a decrease on the crosslink density, retaining the 3D cross-linked structure. Vitrimers are able to undergo a rearrangement of the initial network topology by the breaking of a covalently crosslinked bond followed by the instant creation of a new covalent bond in other position of the polymer chain. In this context, this type of dynamic crosslinked system allows the material to flow at high temperatures and to be reprocessed.

It has been found that one effective strategy to confer reprocessing capabilities to a fossil-based thermosetting polymer is to introduce disulfide-containing amines within the polymer network [15-23]. The proposed strategy allowed that the thermosetting polymer undergo a network rearrangement while the 3D structure is maintained without a sudden drop in viscosity. Hence, in terms of applications this strategy is more adequate than the reversible and dissociative approach of e.g, the well-known Diels-Alder reaction. This highlighted disadvantage is because

through the Diels-Alder strategy the crosslinked network depolymerizes and as result an undesirable loss of the polymer stability is obtained [24-26].

Besides, most of the studies on polymeric vitrimers and dynamic networks have been performed from fossil-based epoxies that have hazardous effects on human health and ecotoxicity. Therefore, the exploitation of renewable resources, such as plant oils [27], is necessary and timely from both academic and industrial points of view, with the sustainable development of epoxidized precursors in line with the criteria established by the new EU chemical regulations, RoHS and REACH [2]. These epoxidized precursors can be used in the synthesis of partially or fully biobased thermosetting polymers with improve thermomechanical properties. For instance, aromatic epoxidized oils such as cardanol [28, 29], soybean [30] and eugenol [31-34] have been reported as proper renewable substitutes of DGEBA. Nevertheless, chemically cross-linked plant-derived epoxy resins are also nonrecyclable.

On the basis of literature research, recently, an eugenol-derived epoxy (Eu-EP) has been reported [32, 34] with reshaping, self-healing, and shape memory properties prepared by reacting Eu-EP with succinic anhydride at various ratios in presence of zinc-based catalysts. On the other hand, a metal-catalyzed ESO-based vitrimer was prepared using fumaropimaric acid as a curing agent and zinc acetylacetonate as the transesterification catalyst [35]. Besides, a biobased thermosetting vitrimer from isosorbide-derived epoxy and aromatic diamine containing disulfide bonds has been reported [36]. Nevertheless, these two latter biobased vitrimers did not exhibit thermomechanical properties that are comparable or superior to the well-established fossil-based DGEBA. Hence, the investigation of environmentally friendly alternatives for the development of biobased epoxy with dynamic networks that are in continuous advancement still remains a challenge for a more sustainable polymer industry.

The objective of the current work is the development of a partially biobased aromatic material from eugenol that can be reshapeable, self-healable and recyclable by means of associative dynamic chemistry without catalysts on agreement with principles for a green chemistry. Thermosetting polymers based on synthesized tri(epoxidized-eugenyl) phosphate (TEEP) were prepared. Epoxidized eugenol was selected as the thermosetting matrix to confer high modulus and thermal properties compared with fossil-based DGEBA [37]. A disulfide-containing amine was applied as a curing agent.

Experimental Section

Materials

Eugenol (99%), phosphorus oxychloride (99%), triethylamine (99%), 3-chloroperbenzoic acid (77%), 4-aminophenyl disulfide, DSA (98%) were purchased from Sigma Aldrich France. 3,3'-diaminodiphenyl sulfone, DDS (98%) was purchased from Alfa Aesar.

Synthesis of trieugenylphosphate (TEP)

First, a mixture of eugenol (61 mmol) and triethylamine (61 mmol) in ethyl acetate (100 mL) was prepared and phosphorus oxychloride (20.33 mmol) was added drop by drop at temperatures between 0 and 5°C. The mixture was maintained between 0 and 5°C during 30 min, and then it was stirred at room temperature during 16 hours. Afterwards, the mixture was diluted by adding 100 mL of ethyl acetate and washed several times with 100 mL of deionized (DI) water and one time with 100 mL brine solution. The organic portion was then dried with anhydrous magnesium sulfate and filtered. Finally, the filtrate was distilled under vacuum. The detailed synthesis of TEP and the corresponding characterizations have been previously reported by Caillol et al. [31].

Synthesis of tri(epoxized-eugenyl)phosphate (TEEP)

First a suspension of meta-chloroperbenzoic acid (m-CPBA 77%) (62.7 mmol) in 200mL of ethyl acetate was added drop by drop to a solution of TEP (19 mmol) in 50 mL of ethyl acetate at temperatures between 0 and 5°C. The resulted mixture was maintained at this range of temperature during 30 min, and then it was stirred at room temperature during 24 hours. Afterwards, the solvent in the mixture was evaporated and the excess of m-CPBA was neutralized with a saturated solution of sodium bicarbonate and removed with ethyl acetate. The organic part was washed several times with saturated sodium bicarbonate, brine and deionized water. The organic part was dried with anhydrous magnesium sulfate and filtered. Finally, the filtrate was distilled under vacuum. The detailed synthesis of TEEP has been previously reported by Caillol et al. [31].

Preparation of partially biobased epoxy networks:

a-Partially biobased epoxy network from tri(epoxized-eugenyl)phosphate cured with the dynamic crosslinker (TEEP:DSA)

A eugenol based epoxy system containing exchangeable crosslinks in a dynamic way was prepared by vigorously mixing the TEEP and DSA in a stoichiometric weight ratio (epoxy:N-H=1:1) at 120 °C during 3 min to form a viscous homogeneous mixture. Immediately, the reaction mixture was casted into a preheated Teflon mold of 24x5x1 mm³ at 120 °C, and then hot pressed for 3000 sec at 20 bar. Afterwards the parallelepiped samples were transferred into an oven to continue curing at 120 °C for 1 h and at 150 °C for 2 h and post-cure at 180 for 2 h. Solvent casted films were also prepared.

b- Partially biobased epoxy network from tri(epoxized-eugenyl)phosphate cured with the non-reversible crosslinker (TEEP:DDS)

A eugenol based epoxy system containing non-reversible chemical bonds was prepared by vigorously mixing TEEP and DDS in a stoichiometric weight ratio (epoxy:N-H= 1:1) at 150 °C during 1 min to form a viscous homogeneous mixture. Immediately, the reaction mixture was casted into a preheated Teflon mold of 24x5x1 mm³ at 150 °C and hot pressed for 3000 sec at 20 bar. Afterwards the parallelepiped samples were transferred to an oven to continue curing at 150 °C for 2 h and post-cure at 180 for 2 h. Solvent casted films were also prepared.

Fourier transformed infrared (FTIR)

A blank background was carried out before examining the samples (32 scans were accumulated at a resolution of 4 cm⁻¹) on a Nicolet 380 spectrometer equipped with an ATR diamond module in reflection mode.

Differential scanning calorimetry (DSC)

The glass transition temperature (T_g) of the bio-based epoxy networks before and after curing reaction was determined using a DSC Q 200 (TA Instruments) by scanning the sample (around 3 mg) from 25 to 230 °C at a heating rate of 10°C/min under nitrogen flow (50 mL/min).

Gel content

The gel content of all partially biobased epoxy networks was determined by the solvent extraction method using THF. The sample was weighted and immersed in THF at room temperature during 72h. Afterwards the sample was dry at 70°C in an oven and under vacuum until there was no appreciable weight change. The gel content was calculated using the following equation:

$$GC = \left(\frac{m_2}{m_1} \right) \times 100$$

where m_2 is the mass of the sample after drying and m_1 is the initial mass of the sample.

Thermogravimetric analysis (TGA)

TGA experiments of the biobased epoxy networks were carried out on a TGA Q 5000 apparatus (TA Instruments), from room temperature to 700 °C at a heating rate of 20 °C/min under inert atmosphere to avoid oxidative thermal degradation.

Dynamic mechanical analysis (DMA) and Isothermal stress relaxation

The dynamic mechanical properties of the biobased epoxy networks were characterized using a Discovery HR hybrid rheometer (TA instruments) in torsion mode to determine the storage modulus (G'), loss factor ($\tan\delta$), and the mechanical transition temperatures (T_a). The dimension of the sample was 24x5x1 mm³. The frequency was set at 1 Hz, and the torsional dynamic strain was set at 0.05 %. The value of torsional dynamic strain used was determined by a previous strain sweep experiment to determine the region of linear response where G' was constant. The samples were scanned from 30 to 230 °C at 5°C/min. For the isothermal stress relaxation experiments, a torsional strain of 0.1% was applied and the stress relaxation modulus was monitored as a function of time at temperatures of 130, 200, 210 and 230 °C. When the equipment reached the testing temperature, the sample was allowed to achieve thermal equilibrium during 10 min before measuring.

Crosslinking density

The crosslinking density of TEEP:DSA and TEEP:DDS after post-curing was calculated from DMA results using the following equation [REFERENCE.]:

$$\text{Crosslinking density} = \frac{G'}{3TR}$$

where G' is the storage modulus (MPa), on the rubbery plateau (230°C), T is the temperature in kelvin, R is the universal gas constant (8.314 MPa.cm³/mol K).

Reshaping test

To assess the potential reshaping properties of fully cured partially biobased epoxy network containing dynamically reversible crosslinks, a flat film of TEEP:DSA was covered in Teflon tape and bent over a glass cylinder to take a new shape. Afterwards, this bent-shaped film was heated in an oven at 230 °C for 1 h, the film was finally cooled down to room temperature. In order to confirm the stability of the new shape, a shape memory test was carried out. For shape memory testing, the following deformation-fixation-relaxation cycle was performed: 1) the U-shaped film was heated at 180 °C for about 60 s, 2) the film was then manually deformed to be flat again and cooled at ambient condition until the temporary shape was fixed. 3) The specimen with temporary flat shape was then reheated at 180 °C to examine the shape recovery. The inner diameter as well as the curvature of the deformed specimens were quantified. The recovered angle (θ_r , recorded by drawing the tangents at the two edges of recovered samples) was recorded, and the recovery ratio (R_r) was calculated by $\theta_r/180^\circ \times 100\%$.

Self-healing test

In order to demonstrate the potential healing properties with temperature of the partially biobased epoxy network containing dynamically reversible crosslinks, a TEEP:DSA film was scratched with a razor blade to create a visible crack on the surface by Optical Microscopy (OM). The healing process was performed at 230 °C in a hot plate and the aspect of the film surface was recorded before and after treatment by OM.

Solid-state recycling test

The potential recycling capability of the fully cured biobased epoxy network containing dynamically reversible crosslinks, TEEP:DSA, was demonstrated by welding two small pieces. A small area of the two pieces were superimposed and join together in a hot press at 200 °C for 3000 sec at 20 bar. After the sample was press released and cooled down to room temperature.

Results and Discussion

TEEP:DSA and TEEP:DDS partially biobased epoxy systems were prepared through a two-step synthesis pathway. First, a trieugenylphosphate (TEP) was synthesized by treating eugenol with phosphorus oxychloride. Afterwards, the allylic groups of TEP were epoxidized with m-CPBA to obtain tri(epoxidized-eugenyl)phosphate (TEEP). The physicochemical characterization of TEP and TEEP has been previously reported by Caillol et al. [31], corroborating the disappearance of OH groups of eugenol by the reaction with phosphorus oxychloride to develop the TEP building block as well as the conversion of the double bonds in the TEP for epoxy groups to develop the TEEP bio-based resin. The second step consisted in the generation of the different partially biobased epoxy networks by the thermal curing of the epoxidized precursor with the dynamic (DSA) and non-dynamic crosslinker (DDS) (Scheme 1).

Scheme 1. General overview of the synthesis of the different partially biobased epoxy networks.

The crosslinking reaction of TEEP:DSA system was studied by DSC in order to establish the proper curing protocol. As can be seen from table 1 and figure 1, the epoxy system began to cure at around 100 °C with a maximum curing temperature at around 185 °C. In this sense, the post-curing protocol was set at 180 for 2 h. An increment of T_g was observed, from 7 °C for the uncured system to 193 °C for the post-cured system, corroborating the epoxy network formation. In addition, full crosslinking of TEEP:DSA after post-curing at 180 °C for 2 h was confirmed by the disappearance of the exothermic peak at high temperatures and also because the T_g of the system remained invariable in the second heating scan.

Figure 1. DSC heating scans at 10 °C/min of uncured, cured and post-cured TEEP :DSA partially biobased epoxy systems.

Table 1. Thermal properties of uncured, cured and post cured TEEP:DSA partially biobased epoxy systems.

Sample	T_g uncured system ^(a) (°C)	T_g cured system ^(b) (°C)	T_g post-cured system ^(c) (°C)	T_g post-cured system ^(d) (°C)
TEEP:DSA	7	184	193	194

^(a) T_g value (endset point) obtained from the first heating scan at 10°C/min (-50-200°C)

^(b) T_g value (endset point) obtained from the first heating scan at 10°C/min (25-230°C)

^(c) T_g value (endset point) obtained from the first heating scan at 10°C/min (25-230°C)

^(d) T_g value (endset point) obtained from the second heating scan at 10°C/min (25-230°C)

The crosslinking reaction was also corroborated by FTIR. Figure S2 shows the FTIR spectra for TEEP:DSA before and after curing at 120 °C for 1 h and at 150 °C for 2 h and post-cure at 180 for 2 h. As can be seen, the signals of stretching C-O-C at 850 cm^{-1} and stretching of C-H of the oxirane ring at 3057 cm^{-1} disappeared, demonstrating the formation of the epoxy network of TEEP:DSA.

Figure 2. FTIR spectra of uncured and cured TEEP :DSA partially biobased epoxy systems.

Thermal characterization and gel content evaluation of cured partially biobased epoxy systems after curing.

First, the efficiency of the curing reaction of all the biobased epoxy systems was evaluated by gel content estimation using the solvent extraction method. Table 1 shows that high gel content values in THF were obtained for all the partially biobased epoxy networks indicating that the synthesized thermosets were effectively crosslinked. No appreciable weight loss was detected after the solvent extraction.

Table 2. Thermal stability and gel content of TEEP:DSA and TEEP:DDS partially biobased epoxy systems.

Sample	Gel content (%)	T _{d,5%} (°C)	T _{d, peak} (°C)	Residual yield ^(a) (°C)
TEEP:DSA	99	295	327	55
TEEP:DDS	99	323	345	58

(a) Residual yield after TGA at 700°C in nitrogen atmosphere

Figure S1 shows the thermograms for both partially biobased epoxies after post-curing. All degradation temperatures are presented Table 2. The degradation temperatures selected for the evaluation are at 5 wt.% of weight loss and at the maximum degradation temperature. The maximum degradation temperature is related with the maximum peak of the derivative of the weight loss. As can be seen, the thermal decomposition of TEEP:DSA and TEEP:DDS did not show weight loss higher than 5 wt% at temperatures up to 290 °C. The onset thermal decomposition of both partially biobased epoxy networks has been ascribed to the chemical breakage of the methoxy groups from eugenol chains [34]. As can be seen, TEEP:DSA showed a slightly lower degradation temperature than TEEP:DDS. This behavior can be ascribed to the presence of less stable disulfide bonds in contrast with C-C bonds [36]. Interestingly, all the partially biobased epoxy networks begin to degrade above around 100 °C from their corresponding T_g, a good indicative that TEEP:DSA epoxy networks can be reprocessed at high temperatures. It is a key point for vitrimer applications as covalent adaptable networks triggered by temperature. On the other hand, all the systems showed high residual yield values after submit the samples at 700°C. From table 1, it can be pointed out that the thermal stability and residual yield of the biobased epoxies depend mainly on the phosphorus content [37]. On the

basis of literature research [34], residual yield of 13.8 wt% has been found for DGEBA:DDS by means of thermogravimetric analytical curves up to 800 °C under N₂, meaning a four times increment for TEEP:DDS (58 wt%) respect to fossil-based DGEBA:DDS. Hence, these developed partially biobased epoxy networks are suitable materials for applications where fire retardant property is required, such as structural materials for aerospace and transportation.

Dynamic mechanical properties of partially biobased epoxy systems.

The stiffness and damping properties of the fully cured partially biobased epoxy networks were evaluated by torsional dynamic strain experiments in order to follow the temperature dependence of the storage modulus (G') and loss tangent ($\tan \delta$) of TEEP:DSA and TEEP:DDS. DMA spectra are shown in Figure 3 (a) and (b). The values of the thermomechanical properties for each partially biobased epoxy network are summarized in Table 3. The reported mechanical relaxation temperatures (T_a) were taken at the maximum of the $\tan \delta$ peak and then associated to the glass transition temperature (T_g).

Table 3. Thermomechanical properties of TEEP:DSA and TEEP:DDS partially biobased epoxy systems.

Sample	G' at 35°C (Pa)	G' at 230°C (Pa)	T_a (°C)	Crosslink density (mol/cm ³)
TEEP:DSA	9.28E8	5.73 E7	192	0.00457
TEEP:DDS	1.24E9	5.75 E7	197	0.00459

Figure 3. DMA spectra for the storage modulus (G') (a) and loss factor ($\tan \delta$) (b) versus temperature of TEEP:DSA and TEEP:DDS partially biobased epoxy systems.

From DMA spectra, it can be concluded that the stoichiometric formulation used to prepare all the systems, with a high renewable carbon content of around 70 wt.%, permits the development of partially biobased epoxy networks with higher T_g and comparable stiffness than that of conventional fossil-based systems. For instance, Odriozola et al. [21] have obtained T_g at around 130°C for the fossil-based DGEBA cured with DSA in a stoichiometric weight ratio. The high T_g values in the partially biobased epoxy systems from this work compared with fossil-based DGEBA cured with DSA are due to a higher oxirane functionality in the TEEP monomer compared to DGEBA monomer. On the other hand, the value of storage modulus at glassy state of TEEP:DSA and TEEP:DDS were comparable with the value of DGEBA:DDS found in the literature [38]. As expected, identical crosslinking density was obtained for TEEP:DDS and TEEP:DSA due to the similarity in the molar mass, length and chemical architecture of the dynamic and non-dynamic cross-linkers, this result is in agreement with the gel content reported for TEEP:DDS and TEEP:DSA in table 2.

Thermal stress relaxation of disulfide exchange reactions of partially biobased epoxy systems.

The time-dependent shear stress at various temperatures was monitored for TEEP:DSA and TEEP:DDS by steady strain experiment using a rheometer in torsion mode. This test was carried out in order to study the capability of the partially biobased epoxy system cured with the dynamic crosslinker to be malleable and thermally reprocessed. The evaluated temperatures were selected in order to be above and below the corresponding T_{α} . This procedure allowed establishing the appropriate activation temperature and rate of cross-link reorganization in the dynamic covalent network [39]. It is expected that the disulfide chemical bonds present in the epoxy network can be exchanged efficiently between different positions of the polymer chains at a specific temperature. For this purpose, the strain was maintained at a fixed value to monitor the viscoelastic behavior of the material by measuring the thermal stress relaxation with time. The Maxwell model for viscoelastic fluids was applied in order to define the stress relaxation time (τ^*) for each temperature. The model outlines that the time for stress relaxation is the time needed for the modulus to fall to $1/e$ of its initial value, in other words $G(t)/G_0=0.37$, where $G(t)$ is the value of relaxed modulus at a fixed time and G_0 is the unrelaxed modulus. The Arrhenius equation was employed to evaluate the minimum energy to start disulfide bond exchange reactions (E_a), as follows:

$$\tau^* = \tau_0 \exp \left(\frac{E_a}{RT} \right) [3]$$

where τ^* is the relaxation time, τ_0 is the characteristic relaxation time, E_a is the activation energy, R is the gas constant and T is the temperature.

Table 4. Relaxation times (τ^*), activation energy (Ea), and topology freezing temperature (Tv) of TEEP:DDA.

Figure 4. Evolution of normalized relaxation modulus, $G(t)/G_0$, for TEEP:DSA and TEEP:DDS at different temperatures. The dotted line shows the characteristic relaxation time (a) and Arrhenius analysis of the characteristic relaxation time τ^* versus $1000/T$ (b).

As can be seen from Figure 4 and table 4, the relaxation time of TEEP:DSA decreased with temperature according to the Arrhenius law (equation 3), confirming the vitrimeric behaviour of this system with a disulfide bonds exchange activation energy-dependence (E_a) of around 17 kJ/mol (calculated from the slope of the Arrhenius plot obtained from the relaxation times τ^* at different temperatures). As a result, the time-dependent shear stress shows a macroscopic flow without permanent loss of material properties. The observed stress relaxation time was around 37 s at 230 °C, corresponding to a fast disulfide bond exchange rate due to an increase in the segmental mobility at a temperature around 40 °C higher than the T_g . The fast stress relaxation obtained for TEEP:DSA is in the range of the fastest stress relaxation time reported for rigid and

highly cross-linked materials [REFERENCES]. At 130 °C, temperature below the T_g of the system, it was not observed a considerable drop in the modulus even after 3600 s of testing, because this temperature was not higher enough to induce segmental motions in the epoxy network and as consequence the disulfide bonds are frozen. This behavior at 130 °C can be explained with the estimation of the hypothetical topology freezing temperature (T_v) that is the temperature in which the material experience a transition from solid to liquid due to a bond exchange reaction in a dynamic network, and this transition is assumed to occur when the viscosity becomes higher than 10^{12} Pa.s [REFERENCES]. In this sense, a T_v value of around 151 °C (below the T_g) was theoretically determined by the estimation of τ^* with the Maxwell equation (equation 4) and the extrapolation of the Arrhenius' fitted line at the estimated τ^* .

$$\eta = G \cdot \tau^* \quad [4]$$

where, η is the viscosity (10^{12} Pa.s), G is the shear viscosity modulus ($G=G'/(2(1+\nu))$), with $\nu \approx 0.5$, the Poisson's ratio and τ^* is the relaxation time.

The macroscopic flow observed for TEEP:DSA at 230 °C on very short time is a prove that this partially biobased epoxy can be heat-processable like thermoplastics in order to be reshaped, healed and even recycled by the welding of fragmented pieces. In addition, an isotherm weight loss experiment carried out by TGA at 230°C under oxidative air atmosphere during 1h showed a weight loss of only around 2%. Indicating a good thermal stability during a reshaping, healing and recycling processes.

On the other hand, it was observed that TEEP:DDS did not show stress relaxation at 230°C, corroborating that the macroscopic flow was only possible in the epoxy network able to carried out disulphide exchange reactions.

Reshaping tests of partially biobased epoxy systems.

To study the reshaping ability of the partially biobased epoxy system containing the dynamic crosslinker, a flat film of TEEP:DSA was reshaped in order to it takes a new permanent bent-shape configuration. As can be seen in Figure 5, the TEEP:DSA film successfully changed its shape after the thermal treatment at 230°C, a temperature above its T_a or activation temperature. This ability can be explained by the thermally induced dynamic exchange reaction of disulfide bonds that cause the rearrangement of the covalent crosslinked network topographies. For the shape memory studies to verify the stability of the shape changeability, first, the sample with “U” bent-shape was flattened at temperature above T_g , and then it was cooled below T_g to fix the temporary flat shape of the film. Afterward, the film was transferred to a heating plate with a temperature of around 180 °C (T_g) to promote the recovery of the “U” bent-shape (permanent shape after reshaping), the recovery ratio was around 99% (Figure S2). The stability of the reshaped film was confirmed in a range of temperature between 25 to 180°C.

Figure 5. Thermal bent-shaped processing and photograph of the initial and final sample.

For comparison purposes, a flat film of TEEP:DDS without dynamic properties was reshaped with the same procedure. In this case, the film totally recovered the original flat shape at temperatures around the T_g of the system (Figure S3), corroborating that the covalent crosslinked network topographies did not change and the new “U” bent-shape can only be temporarily fixed at temperatures below the T_g . Another shaping test was carried out by hot pressing fully cured specimens of TEEP:DSA and TEEP:DDS in order to form a thinner film. It was observed that just the partially biobased epoxy containing the dynamic crosslinker was able to be reshaped (Figure S4) while the partially biobased epoxy containing the non-reversible crosslinker was reduced to dust after the shaping test (Figure S5). In this sense, the occurrence of macroscopic flow at high temperature, observed in the thermal stress relaxation test, due to the novel dynamic properties arising from the disulphide exchange reactions is a potential strategy to confer reprocessable characteristics to biobased thermosetting polymers.

Macroscopic thermal self-healing test of partially biobased epoxy system

To show the ability of developed partially biobased epoxies containing dynamic crosslinker to be repaired by thermal treatment and as result to increase their efficient lifetime, a scratched specimen was heated at 230 °C, a temperature above its T_a or activation temperature, under pressure-free condition (Figure 6).

Figure 6. Thermal self-healing of TEEP:DSA under stress-free condition. The appearance of the crack depending of repairing time was analyzed at the same site in the sample surface: (a) before and (b) after treatment. Scale bar of OM images = 500 μm .

This treatment stimulates the softening of the polymer by means of the exchange reaction of disulfide bonds to re-joint the cracked surfaces through the development of new covalent bonds at the interface of the damage surface. As can be seen from OM evaluation (Figure 6), a scratched TEEP:DSA surface shows that the crack gradually disappear when it was heated at 230°C during 60 min, indicating the excellent repairing potentials of these novel biobased epoxies. On the contrary, a scratched TEEP:DDS surface did not show self-healing behavior (Figure S6). Corroborating that the softening and welding observed for TEEP:DSA was possible because the disulfide bonds exchange reaction at high temperatures.

Recycling test of partially biobased epoxy systems

Here, we demonstrated that fragmented pieces of TEEP:DSA can be potentially welded by a simple hot pressing process at 230 °C to form a new manufactured material. In addition, the two re-connected pieces presented a good adhesion after manual bending (Figure 7). For comparison purpose, fragmented pieces of TEEP:DDS were submitted to the same recycling process as TEEP:DSA. Nevertheless, it was observed that after treatment the biobased epoxy cured with the non-reversible crosslinker was completely cracked in small pieces (Figure S7). This result confirms that the introduction of dynamic properties in the partially biobased epoxy permit the welding of the two surfaces because novel crosslinked bonds can be created across the interface (bridges) of the pieces when they are brought into contact by hot pressing. This welding capability of TEEP:DSA by hot pressing without the need of an external adhesive can allow promising recycling applications by transforming its plastic waste to potential raw materials.

Figure 7. Cutting (a) and welding by hot pressing of TEEP:DSA at 230°C (b). The sample was manually bent to show the good cohesion between the welded pieces (c).

Conclusions

In this work we successfully synthesized a sustainable dynamic thermoset with high renewable carbon content based on epoxidized eugenol oil crosslinked with an aromatic diamine containing

disulfide functional groups. The dynamic eugenol-derived epoxy, TEEP:DSA, revealed comparable stiffness and higher T_g values than that fossil-based DGEBA. Thermal stress relaxation of TEEP:DSA confirmed the associative crosslink exchange reactions by means of disulfide bonds rearrangement at high temperatures.

It was demonstrated that the proposed strategy of integrating dynamic covalent crosslink in the eugenol-derived epoxy provides highly promising reshaping, self-healing and recycling capabilities. Such a sum of properties is not obtained with conventional thermosets, suggesting a way to increase eugenol-based epoxies lifetime and prevent their waste disposal into the environment. As result, contribute achieving the EU Product Policy Framework of the Circular Economy targets.

Dynamic networks based on eugenol-derived epoxies are very interesting for sustainable fields in e.g., coating and structural systems, for a large range of applications such as transportation, aerospace and building. However, the applicability of TEEP:DSA needs to be now fully demonstrated in real situations by the quantitative evaluation of the recycling and self-healing efficiency in terms of its mechanical properties after several processing cycles.
