Contact interactions of a muon, an electron and two photons can contribute to the decay $\mu \rightarrow e\gamma\gamma$, but also to the conversion of a muon into an electron in the electric field of a nucleus. We calculate the $\mu \rightarrow e$ conversion rate, and show that for the coefficients of operators involving the combination $F\bar{F} \propto |\vec{E}|^2$ (as opposed to $FF \propto \vec{E} \cdot \vec{B}$), the current bound on $\mu \rightarrow e$ conversion is more sensitive than the bound on $\mu \rightarrow e\gamma\gamma$.

DOI: 10.1103/PhysRevD.102.115043

I. INTRODUCTION

The observed neutrino masses imply the existence of contact interactions where charged leptons change flavor. This is referred to as (charged) lepton flavor violation (CLFV) and is reviewed for muon decays in, e.g., [1]. Current constraints on several $\mu \leftrightarrow e$ flavor changing processes are restrictive, and experiments under construction [2–4] aim to reach $\text{BR} \sim 10^{-16}$. Some bounds and future sensitivities are given in Table I.

If CLFV is discovered, experimental bounds on, or observations of, a multitude of independent processes would assist in discriminating among models. This motivates our interest in the less commonly considered contact interactions involving a muon, an electron and two photons. Such interactions could mediate various processes, such as $\mu \rightarrow e\gamma\gamma$ and $\mu \rightarrow e$ conversion in the electric field of a nucleus. The rate for $\mu \rightarrow e\gamma\gamma$ was calculated by Bowman, Cheng, Li and Matis (BCLM) [11], whose results are reviewed in Sec. II, and an experimental search with the Crystal Box detector obtained $\text{BR}(\mu \rightarrow e\gamma\gamma) \leq 7.2 \times 10^{-11}$ [7]. Similar contact interactions, involving two photons but dark matter instead of leptons, have been studied in [12–15].

We will parametrize CLFV interactions via contact interactions involving Standard Model (SM) particles. This would be appropriate if the new particles involved in CLFV are heavy, but may not be generic for $\mu \rightarrow e\gamma\gamma$. This decay could be mediated by $\mu \rightarrow ea$ [16] followed by $a \rightarrow \gamma\gamma$, where $a$ is a light (pseudo) scalar such as an axionlike particle [17]. Recently, the MEG experiment searched for collinear photons from this process [18]. They found that the branching ratio of $\mu^+ \rightarrow e^+a, a \rightarrow \gamma\gamma$ is smaller than $O(10^{-11})$ when the mediator $a$ has a mass of 20–45 MeV and a lifetime below 40 ps.

In this manuscript, we calculate the $\mu \rightarrow e$ conversion rate induced by contact interactions of $\mu$, $e$ and two photons. Section II introduces the basis of operators (previously given by BCLM [11]), and gives their contribution to $\mu \rightarrow e\gamma\gamma$. The operators are of dimension seven and eight; we focus on the dimension seven operators, which can arise from loop corrections to dimension six scalar operators. Our calculation of $\mu \rightarrow e$ conversion mediated by the $\bar{e}uFF$ operator is presented in Secs. III and IV, where we first calculate the interaction of the leptons with the classical electromagnetic field, then in Sec. IV find a surprisingly large “short distance” loop interaction of two photons with individual protons. The final discussion section integrates our results in the usual expression for the spin independent branching ratio of $\mu \rightarrow e$ conversion, and discusses the current and future sensitivity to the $\bar{e}\mu FF$ operator coefficients at the experimental scale. Appendix A considers loop contributions to the $\bar{e}\mu FF$ operator and its relation to dimension six LFV.

II. NOTATION AND REVIEW

A set of QED-invariant operators that could mediate the decay \( \mu \rightarrow e\gamma \gamma \) was given by Bowman, Cheng, Li and Matis (BCLM) [11]:

\[
\delta \mathcal{L} = \frac{1}{\bar{\mu}^3} \left( C_{FF,L} \bar{e} P_L \mu F_{a\bar{b}} F^{a\bar{b}} + C_{FF,R} \bar{e} P_R \mu F_{a\bar{b}} F^{a\bar{b}} + C_{FF,\bar{L}} \bar{\epsilon} P_L \mu F_{a\bar{b}} F^{a\bar{b}} + C_{FF,\bar{R}} \bar{\epsilon} P_R \mu F_{a\bar{b}} F^{a\bar{b}} \right) + \frac{1}{\bar{u}^3} \left( C_{VFF,L} \bar{\epsilon} P_L F^{a\bar{b}} \partial_\rho F_{a\sigma} + C_{VFF,R} \bar{\epsilon} P_R F^{a\bar{b}} \partial_\rho F_{a\sigma} + C_{V\bar{F},L} \bar{\epsilon} P_L F^{a\bar{b}} \partial_\rho \bar{F}_{a\sigma} + C_{V\bar{F},R} \bar{\epsilon} P_R F^{a\bar{b}} \partial_\rho \bar{F}_{a\sigma} \right) + [\text{H.c.}],
\]

where two changes have been made to their notation: the new physics scale in the denominator is taken to be the Higgs vacuum expectation value \( v \approx m_\mu \), with \( 2\sqrt{2} G_F = 1/v^2 \) (BCLM took \( m_\mu \)), and we use chiral fermions, because this facilitates matching onto the full SM at the weak scale, and because the outgoing electrons are relativistic so \( \approx \) chiral.

This basis of operators is constructed to include all possible Lorentz contractions that give the desired external particles (there is no tensor, because there is no two-index antisymmetric combination of \( FF \) or \( \bar{F} \) to contract with \( \bar{\epsilon}\sigma\mu \)), so corresponds to a general parametrization of the interaction at lowest order in a momentum expansion. The resulting operators are of dimension seven and eight.

Curiously, all the operators of Eq. (1) induce a matrix-element-squared for \( \mu(P_\mu) \rightarrow e(P_e) + \gamma(k) + \gamma(q) \) that is proportional to [11]

\[ |\mathcal{M}|^2 \propto P_\mu \cdot P_e (k \cdot q)^2, \]

giving a branching ratio

\[ BR(\mu \rightarrow e\gamma\gamma) = C^2 \frac{2m_\mu^2}{5v^2}, \]

where

\[ \text{The tensor operator considered in [14] should vanish.} \]
to observables will be suppressed by additional factors of $E_{\text{exp}}/\Lambda_{\text{NP}}$. However, some of the operators of Eq. (1) can arise at $\mathcal{O}(1/\Lambda_{\text{NP}}^2)$ in a CLFV new physics model, with a SM mass scale providing the additional dimensions in the denominator. For example, if the scalar operators

$$ C_{\mu \mu}^{\text{ew}} \equiv (\bar{\psi} P_X \mu)(\bar{\mu} P_X \psi), \quad C_{\mu \mu}^{\text{w}} \equiv (\bar{\psi} P_Y \mu)(\bar{\mu} P_Y \psi) \quad (5) $$

are present in the Lagrangian as $\delta \mathcal{L} = \frac{1}{\Lambda_{\text{NP}}^2} (C_{\mu \mu}^{\text{ew}} \mathcal{O}_{S,XX}^{\mu \mu} + C_{\mu \mu}^{\text{w}} \mathcal{O}_{S,XY}^{\mu \mu})$, then at a heavy fermion mass scale $m_\psi$, they match onto the two-photon operator $\mathcal{O}_{F,F,X}$ via the diagram of Fig. 1, with coefficient

$$ C_{F,F,X} = -\sum_x (C_{\mu \mu}^{\text{ew}} + C_{\mu \mu}^{\text{w}}) \frac{e^2 N_x \alpha_e}{12 \pi m_\psi \Lambda_{\text{NP}}^2} \quad (6) $$

where $N_x = 3$ for heavy quarks, and is one otherwise. This result is related to the conformal anomaly [20], and is the QED version of the matching of scalar heavy quark operators onto gluons, performed by Shifman, Vainshtein and Zakharov [21] (the $\bar{e}\mu G G$ operators were included in $\mu \to e$ conversion by [22]).

The dimension eight two-photon operators $\mathcal{O}_{F,F,X}^{\text{ew}} = \bar{\psi} \gamma^a P_X \mu F^{a\sigma} \partial_\sigma \bar{\mu} \psi$ appear more difficult to obtain at $\mathcal{O}(1/\Lambda_{\text{NP}}^2)$. Furry’s theorem says that dimension six vector operators, such as $(\bar{e} \gamma^a P_X \mu)(\bar{\mu} \gamma_a \psi)$, do not match onto $\mathcal{O}_{F,F,X}^{\text{w}}$ via the diagram of Fig. 1, because an odd number of vector current insertions appear on the fermion loop. Writing the loop of Fig. 1 with external legs amputated and an axial heavy fermion current $(\bar{\psi} \gamma^a P_X \mu)(\bar{\mu} \gamma_a \psi)$ in the grey blob, gives a vacuum matrix element that is even under charge conjugation, but odd under CP. Analogously to Furry’s theorem, it should vanish in a CP invariant theory, so we do not calculate this diagram in the approximation of CP invariance.

In the next sections, we attempt to calculate the contribution of the scalar $\mathcal{O}_{F,F,X}$ operators to coherent $\mu \to e$ conversion. The new physics scale is not required to be particularly high: Sec. III considers the “long-range” classical electromagnetic field of the nucleus, and should be valid for $\Lambda_{\text{NP}}$ such that $\mathcal{O}_{F,F,X}$ is a contact interaction at the muon mass scale. Section IV is a QED loop calculation involving protons, which requires $\Lambda_{\text{NP}} \gg m_\mu$. In Appendix A, we will reconsider the case of $\Lambda_{\text{NP}} \gg m_\mu$. We do not consider the contribution of the dimension eight operators; if new physics scale is high, their contribution to $\mu \to e$ conversion would be relatively suppressed by $\mathcal{O}(E_{\text{exp}}^2/\Lambda_{\text{NP}}^4)$ compared to that of dimension six LFV operators, and we are not aware of a motivated light new physics model that induces these operators.

III. THE $\mu \to e$ CONVERSION RATE IN THE CLASSICAL ELECTRIC FIELD

We consider the coherent $\mu \to e$ conversion described by the first two terms of Eq. (1). Assuming that the muon and the outgoing electron are independently described by their wave functions in a Coulomb potential, the transition matrix is

$$ \mathcal{M} = \frac{1}{v^3} \int d^3 r \bar{\psi}_e(r) (\mathcal{C}_{F,F,L} P_L + \mathcal{C}_{F,F,R} P_R) \times \psi_\mu^{1s}(r) (|F_{\text{qf}} F^{q\bar{q}}| N), \quad (7) $$

where $\psi_\mu^{1s}$ and $\psi_e$ are respectively the wave functions of a $1s$ bound muon and the outgoing electron. Here, we omit spin indices for simplicity. $|N\rangle$ denotes the ground state of a nucleus. For an ordinary nucleus, we can safely assume that the electric field $E(r)$ is spherically symmetric and the magnetic field is negligible.

We approximate the hadronic matrix element with a classical field strength as:

$$ \langle N|F_{\text{qf}} F^{q\bar{q}}|N\rangle = -2 \langle E(r) \rangle^2. \quad (8) $$

Diagrammatically, this corresponds to assuming that both exchanged photons carry three-momentum but no energy (giving a Coulomb potential), and neglects excited intermediate states for the nucleus. It can be compared to the approximation of Weiner and Yavin [13] for dark matter scattering on nuclei, where the nucleus is treated as a particle of charge $Z$ in heavy quark effective theory, with a form factor to account for its finite size.\(^2\)

With the amplitude $\mathcal{M}$, the conversion probability is given by

$$ d\Gamma_{\text{conv}} = \frac{d^3 p_e}{(2\pi)^3 2E_e} (2\pi) \delta(E_e - E_e^{\text{conv}}) \sum_{\text{spins}} |\mathcal{M}|^2, \quad (9) $$

where the summation includes spin averaging of the initial state, and $E_e^{\text{conv}}$ is the energy of the signal electron, given by $E_e^{\text{conv}} = [(m_N + m_\mu - B_\mu)^2 - m_N^2 + m_\mu^2]/2(m_N + m_\mu - B_\mu)$. Here $B_\mu$ is the binding energy of initial muon in the muonic

\(^2\)This approach is inconvenient in our case because the wave functions of the electrically charged muon and electron are easier to include in position space.
atom. The lepton wave functions \( \psi_e (e = e, \mu) \) obey the Dirac equation in a nuclear Coulomb potential; our formulation below follows [23,24].

For a spherically symmetric potential, one can represent the wave function of the bound muon as

\[
\psi_\mu^{1s}(r) = \left( G(r) \chi_{s1}^\mu (\hat{r}) \right),
\]

where \( \chi \) is a two-component spherical spinor. The differential equations for the radial wave functions \( G(r) \) and \( F(r) \) are obtained from the Dirac equation as follows,

\[
\frac{dG(r)}{dr} - (E_\mu + m_\mu + eV_C(r))F(r) = 0, \\
\frac{dF(r)}{dr} + \frac{2}{r} F(r) + (E_\mu - m_\mu + eV_C(r))G(r) = 0.
\]

The nuclear Coulomb potential \( V_C \) is calculated with a nuclear charge density \( \rho \) as,

\[
V_C(r) = \int_0^\infty dr' r'^2 \rho(r') \left[ \frac{\theta(r - r')}{r} + \frac{\theta(r' - r)}{r'} \right].
\]

For the nuclear density, we adopted two different models, the two-parameter-Fermi distribution (2pF) and three-parameter-Gaussian distribution (3pG), given by

\[
\rho_{2pF}(r) = \frac{\rho_0}{1 + \exp\left(\frac{r - \rho_0}{\sigma_0}\right)}, \\
\rho_{3pG}(r) = \frac{\rho_0(1 + \omega_0 r^2)}{1 + \exp\left(\frac{\rho_0}{\omega_0}\right)}.
\]

The normalization has been used such that \( Z e = 4\pi \int_0^\infty \rho(r)^2 dr \) with the normalization factors \( \rho_0 \) for each type of distribution. The parameters, \( \alpha, c \) and \( z \), are listed in Refs. [25,26].

For simplicity of formulation, we express the wave function of the outgoing electron of momentum \( \hat{p}_e \) using the partial wave expansion:

\[
\psi_e(r) = \sum_{l, j, m} 4\pi i^{l+1} \langle l_m, 1/2, s_e | j_k, \nu \rangle Y_{l_k}^{m*} (\hat{p}_e) \\
\times e^{-i \delta_k} \left( g^f(\hat{r}) \chi_{s1}^\nu (\hat{r}) \right),
\]

where \( j_k \) and \( l_k \) are the total and orbital angular momentum, respectively. We introduced an integer quantum number \( \kappa \) that runs from \(-\infty \rightarrow \infty \) skipping \( 0 \), and determines \( j \) and \( l \)

\[ j_k = |\kappa| - 1/2 \quad \text{and} \quad l_k = j_k + \kappa/2 |\kappa|. \]

Due to angular momentum conservation, only the waves with \( \kappa = \mp 1 \) contributes to \( \mu \rightarrow e \) conversion. \( \delta_e \) is a phase shift of the \( \kappa \) partial wave, and the incoming boundary condition is taken from [24], \( \langle l_m, 1/2, s_e | j_k, \nu \rangle \) is the Clebsch-Gordan coefficient, and \( Y_{l_k}^{m*} (\hat{p}_e) \) is a spherical harmonic. The radial Dirac equations for each partial wave are

\[
\frac{dg^f(r)}{dr} + \frac{1 + \kappa}{r} g^f(r) - (E_e + m_e + eV_C(r))f^s(r) = 0, \\
\frac{df^s(r)}{dr} + \frac{1 - \kappa}{r} f^s(r) + (E_e - m_e + eV_C(r))g^f(r) = 0.
\]

The normalization of the wave functions is the same as Ref. [23].

Then the conversion probability is

\[
\Gamma_{\text{conv}} = 16G^2_F m^5 \left\{ \left| \frac{m}{v} (C_{FF,L} + C_{FF,R}) F_A^- \right|^2 \\
+ \left| \frac{m}{v} (C_{FF,L} - C_{FF,R}) F_A^+ \right|^2 \right\}
\]

where the overlap integrals \( F_A^- \) and \( F_A^+ \) for a target nucleus \( A \) are

\[
F_A^- = \frac{1}{\sqrt{2m^3_F}} \int_0^\infty dr r^2 \{ g^{-1}(r) G(r) - f^{-1}(r) F(r) \}, \\
F_A^+ = \frac{1}{\sqrt{2m^3_F}} \int_0^\infty dr r^2 \{ f^{-1}(r) G(r) + g^{-1}(r) F(r) \}.
\]

Neglecting the electron mass, we have \( g^{-1} = -f^{-1} \) and \( f^{-1} = g^{-1} \), so \( F_A^+ = F_A^- \equiv F_A \). For instance, \( F_A \) for aluminum (\( Z = 13 \)) and gold (\( Z = 79 \)) are \( 3.8 \times 10^{-4} \) and \( -6.1 \times 10^{-3} \), respectively, \( F_A \) for other targets are listed in Appendix B, and the absolute values are plotted in Fig. 2.

A few nuclei are modeled by both the 2pF and 3pG distributions, in which case we give the results with the latest distribution. Apart from the dip around \( Z = 38 \) (discussed below), different distribution models lead to the same results within \( O(1)/% \) accuracy. The magnitude of \( F_A \) continues to grow at large \( Z \) (unlike other overlap integrals [23]), because the squared electric field of heavy nuclei \( E(r)^2 \propto Z^2 \).

In Fig. 2, one sees a dip in the overlap integral in the range \( 30 \lesssim Z \lesssim 50 \). In order to interpret this cancellation, the integrand of \( F_A \) is plotted as a function of radius in Fig. 3 for \( Z = 13, 38, \) and 79. The oscillations arise from the electron wave function \( g^{-1} \), whose first node is at
r \approx \pi/m_\mu \approx 5.8 \text{ fm.} \] Since the electric field is maximized around the nuclear surface, there is a significant cancellation between the interior and exterior contributions to the integral when the first node of $g^{-1}$ is close to the nuclear radius. As a result, the overlap integral changes sign at 35 \lesssim Z \lesssim 40, where the nuclear radius is about 5.5 fm.

However, the precise prediction of the dip is difficult, since the overlap integral at 30 \lesssim Z \lesssim 50 is very sensitive to the nuclear model, and some parameters in the muonic atom (such as the muon binding energy at $O(1)\%$ level). In order to reliably predict $F_A$ for these targets, it would be necessary to model the nuclear distributions with considerable accuracy.

This interesting $Z$ behavior could be a signature of the $O_{FF,X}$ operators, if their contribution to the $\mu \to e$ conversion rate is dominant. For this reason we exhibit it. However, as discussed in the next section, there is a comparable loop contribution, which arises provided that the $\mu e\gamma\gamma$ interaction remains a contact interaction up to scales of a few GeV.

### IV. TWO-PHOTON EXCHANGE WITH A PROTON

The nuclear matrix element of the $FF$ operator involves the expectation value of two nucleon currents, which can be challenging to calculate. If the nucleus is represented as a nonrelativistic bound state of protons (and neutrons), then Wick contractions give two diagrams for the interaction of the $O_{FF,X}$ operator with the nucleus, which are illustrated in Fig. 4. The sum of both diagrams was calculated in the previous Sec. III, in the approximation that the protons remain in their energy levels of an external nuclear potential. This implies that the photons only carry three-momentum, so correspond to the Coulomb potential (which can be checked in the bound state formalism of Appendix B of [27]). This neglects excited intermediate states of the nucleus, which are possible although the final state nucleus should be in the ground state, in order to contribute to coherent $\mu \to e$ conversion. (We also neglect correlations between the two protons, which were considered in [15].)

In this section, we focus on the left diagram, where both photons interact with the same proton, and estimate the contribution of off-shell photons via the renormalization group equations (RGEs) of QED below the proton mass scale. At first sight, this diagram appears negligible, because it is loop-suppressed ($\propto 1/(16\pi^2)$), and benefits from only one factor $Z$ enhancement, as opposed to $Z^2$ for the tree diagram on the right.

In the RGEs of QED, the $FF$ operator can mix to scalar operators $m_\nu O_{SXX}^{\mu\nu}$, $m_\pi O_{SXY}^{\mu\pi}$ [defined in Eq. (5)], for $\psi$ a charged point particle. This corresponds to the log-enhanced part of the loop where both photons interact with the same proton, can be reliably computed in EFT, and was considered in [14] for $\psi$ a heavy quark. In an EFT of leptons and hadrons below 2 GeV, we apply this result for $\psi$ a proton, for scales between 2 GeV and $m_\mu$ the momentum exchange of $\mu \to e$ conversion, which gives

$$\Delta C_{S,XX}^{pp}(m_\mu) = - \frac{6\alpha_{em}m_\mu}{\pi v} \ln \frac{2\text{ GeV}}{m_\mu} C_{FF,X}$$

$$\approx -2.26 \times 10^{-4} C_{FF,X}$$

(21)

where $C_{S,XX}^{pp} = \frac{1}{3} (C_{SXX}^{pp} + C_{SXR}^{pp})$, and $C_{FF,X}$ is evaluated at 2 GeV. This mixing, with $\psi$ a proton, is discussed in [15] but was not included in [14]. It can only be a rough approximation to this loop, because the not-log-enhanced contributions are unknown and difficult to estimate.

We can now calculate the contribution of $C_{FF,X}$ to $\mu \to e$ conversion. The branching ratio is...
where $\Gamma_{\text{cap}}$ is the muon capture rate in a muonic atom [28], $S_A^{(N)}$ and $D_A$ are respectively the overlap integrals in nucleus $A$ of the $\bar{N}N$ nucleon current and the dipole operator [23], $F_A$ is the overlap integral for the FF operator from Sec. III, and “…” represents the vector coefficients that we do not discuss. If the principle source of $\mu \rightarrow e$ flavor change at a scale of 2 GeV is $O_{FF,X}$, then on aluminum and gold, we have

$$\frac{\text{BR}(\mu A \rightarrow eA)}{|C_{FF,L}|^2 + |C_{FF,R}|^2} = \begin{cases} 6.6 \times 10^{-9}[1 + 15]^2 & \text{for } ^{27}\text{Al} \\ 9.1 \times 10^{-8}[1 + 3.8]^2 & \text{for } ^{197}\text{Au} \end{cases}$$

(23)

where between the absolute values is first the tree contribution, then the loop. Unexpectedly, the loop contribution could be larger than the tree for light and heavy nuclei.

Let us briefly discuss how this can occur. Naively, the loop amplitude should be suppressed relative to the tree contribution by $1/(16\pi^2 Z)$. However:

(i) the numerical factor from the loop is large: Eq. (21) is $\sim \alpha \log$, rather than being $\sim 2/\pi^2 \log$.

(ii) the classical amplitude is suppressed by $1/(4\pi)$, because the electric field of a point charge $Z$ is $|E(r)| = Ze/(4\pi r^2)$, so a factor $4\pi$ remains in the denominator when $E^2$ is integrated over the volume of the nucleus. Combined with the first effect, this compensates the $1/16\pi^2$ suppression.

(iii) the FF operator is of dimension seven, so the amplitude is proportional to an energy scale. For the loop, this is the proton mass, whereas for the classical process, it is a combination of the momentum transfer ($m_\mu$) and the inverse nuclear radius, which turns out to be $\sim m_\mu/r^2$. So this ratio of energy scales (over)compensates the $Z$ suppression of the loop.

Alternatively, the second point (and part of the third), can be seen by noticing that the overlap integral $S_A^{(p)}$ is large compared to $F_A$. For simplicity, we assume a uniform proton distribution $\rho \propto Z(\frac{4}{3}\pi R^3)^{-1}$ for a nuclear radius $R \sim 1.1A^{1/3}$ fm. Since the nuclear electric field is maximized around the nuclear surface, we approximate the electric field as one at the surface, $|E|=Ze/(4\pi R^2)$. Hence, the ratio of the overlap integrals is $|F_A/S_A^{(p)}| \approx 2m_\mu^{-1}Ze^{-2}/[Z(\frac{4}{3}\pi R^3)^{-1}] = 2Za/(3m_\mu R) \sim 0.02$ for $^{27}\text{Al}$ (0.06 for $^{197}\text{Au}$), where the overall factor $2m_\mu^{-1}$ covers the typical scale of $\mu \rightarrow e$ conversion and the difference of normalization for overlap integrals between $F_A$ and $S_A^{(p)}$ [23]. That is naive understanding that the overlap $F_A$ is small compared to $S_A^{(p)}$. The numerical calculation tells us that the ratio is 0.02 for $^{27}\text{Al}$ (0.1 for $^{197}\text{Au}$).

Figure 5 shows the branching ratios for targets of atomic number $Z$ normalized by that for aluminum. The branching ratio via the scalar CLFV operator, $O_{S_X} = e\bar{p}X\mu(p)p$, is also shown to highlight the difference of $Z$ dependence. Two features of the overlap integral $F_A$ can be seen: first, it has an additional factor of $Z$, due to the extra $F_{\mu\mu}$, and second, it becomes negative at large $Z$. The first point is illustrated by the dashed line, showing the branching ratio induced only by the tree contribution of the $\bar{e}\mu FF$ operator, which continues to increase at large $Z$. This differs from the high-Z falloff of the branching ratios due to the familiar dipole, scalar or vector operators [23]. The solid line includes the tree and loop contributions of the $\bar{e}\mu FF$ operator, which interfere destructively at large $Z$, where $F_A$ is negative but the scalar overlap integral is positive. This sign difference, combined with the increasing magnitude of $F_A$ at large $Z$, causes the branching ratio to decrease for increasing $Z \gtrsim 50$. The shape and magnitude of this feature differ from the high-Z decrease of dipole, scalar or vector operators [23]. We stress that this feature could be
used to discriminate the $\bar{e}\mu FF$ operator from other CLFV operators.

V. SUMMARY

In this manuscript, we calculated the contribution of low-energy $\bar{e}\mu\gamma\gamma$ contact interactions to $\mu \to e$ conversion on nuclei. We considered the first two operators of Eq. (1), which are CP-even, of dimension seven, and involve $F_{\mu\nu}F^{\mu\nu} \propto |E|^2$. Other possibilities are discussed in Sec. II.

If the $\mu\gamma\gamma$ interaction is a contact interaction at momentum transfers $\sim m_\mu$, then there is a contribution to $\mu \to e$ conversion from the leptons interacting with the electromagnetic field of the nucleus. The calculation is outlined in Sec. III. It relies on the overlap integrals in the nucleus, of the electron and muon wave functions with the electric-field-squared, which are given in Eqs. (19) and (20). This contribution has an interesting and rare feature: it changes sign at intermediate $Z$ (the electric charge of the target nucleus).

If the $\mu\gamma\gamma$ interaction remains a contact interaction at larger momentum transfers $\gtrsim m_\mu$, then the dominant contribution of $O_{FF,X}$ to $\mu \to e$ conversion arises from loop mixing into the scalar proton operator $O_{S,X} = \langle \bar{e}P_s\mu|\bar{p}p\rangle$, as discussed in Sec. IV. Naively, the loop amplitude is suppressed by $1/(16\pi^2Z)$, but overlap integrals, energy ratios, and numerical factors more than compensate, as discussed at the end of the section. The combined tree and loop contributions exhibit a unique $Z$-dependence that could be used to distinguish the $\bar{e}P_s\mu FF$ operator from other operators. The branching ratio for $\mu \to e$ conversion induced by $O_{FF,X}$ is given in Eq. (22), and plotted in Fig. 5.

If the branching ratio for spin independent $\mu \to e$ conversion [23] is expressed as a function of operator coefficients at a scale of 2 GeV, our results for $O_{FF,X}$ can be included as

$$\text{BR}(\mu A \to eA) = \frac{32G_F^2m_\mu^5}{\Gamma_{\text{cap}}} \sum_{x \in \{L,R\}} \left( C_{D,X}^{DA} \frac{D_A}{4} + (9.0C_{S,X}^{uu} + 8.2C_{S,X}^{dd} + 0.42C_{S,X}^{ss})S_A^{(p)} + \cdots \right)$$

where $D_A$ and $S_A^{(N)}$ are the overlap integrals inside the nucleus $A$, with respectively the electric field or the appropriate nucleon ($N \in \{n, p\}$) distribution, which can be found in [23]. $\Gamma_{\text{cap}}$ is the muon capture rate on nucleus $A$ [28], $C_{D,X}$ is the dipole coefficient, $\{C_{S,X}^{\alpha\beta}\}$ are the coefficients of $2\sqrt{2}G_F\langle \bar{e}P_s\mu|\bar{q}q\rangle$, and the “$\cdots$” represents the contributions of vector operators involving a light quark bilinear. This expression uses the quark densities in the nucleon of Refs. [30–33], the gluon density [21,22]

$$\langle N|GG(x)|N \rangle \simeq \frac{8\pi m_N}{9\alpha_s(2 \text{ GeV})}\langle N|NN(x)|N \rangle,$$

and the last term gives the contribution of the operators $O_{FF,X}$, at tree level via the overlap integral $F_A$ tabulated in Appendix B, and via one loop mixing to the scalar proton density ($\ln(2 \text{ GeV}/m_\mu) \approx 3$ is used in the last term).

The SINDRUM II experiment searched for $\mu \to e$ conversion on gold, and obtained the upper bound $\text{BR}(\mu Au \to eAu) \leq 7 \times 10^{-13}$ [9]. If we assume that only the “gauge boson” coefficients are nonzero (at a scale of 2 GeV), this corresponds to the bound:

$$4.9 \times 10^{-8} \gtrsim |0.222C_{D,X} - 0.038C_{GG,X} - 4.8 \times 10^{-5}|,$$

which gives, in the absence of $C_{D,X}$ and $C_{GG,X}$.

\footnotesize

4These are the “EFT” determinations, which are $\sim 50\%$ larger than the lattice results [29].
\[
|C_{FF,X}| \leq 1.0 \times 10^{-3}.
\]

This is a better sensitivity than that given in Eq. (4) from the Crystal Box search for \(\mu \to e\gamma\). Searching for \(\mu \to e\gamma\) nonetheless remains an interesting and complementary channel, because it probes all the operators of Eq. (1). Experimental constraints on \(\mu e\gamma\) coefficients are summarized in Table II.

The upcoming COMET and Mu2e experiments plan to start with an Aluminium target. Combining Eq. (24) and \(F_{\text{Al}} = 3.8 \times 10^{-4}\), we obtain a future sensitivity of

\[
|C_{FF,X}| \leq 7.6 \times 10^{-6} \left(\frac{\text{BR}(\mu \to e\gamma)}{10^{-16}}\right)^{1/2}.
\]

The sensitivity to \(C_{FF,X}\) would be improved by two orders of magnitude with an expected branching ratio of \(\sim 10^{-16}\) on the light target Aluminium.

Finally, we comment on the interest of the \((\bar{e}P_{L,R}\mu)FF\) operators in identifying heavy new physics in the lepton sector. These operators are of dimension seven in the QED \(\times\) QCD-invariant EFT below \(m_{W}\), and dimension eight above. However, they can be mediated by not-so-heavy, feebly coupled pseudoscalars of mass \(m \gg m_{\nu}, m_{\rho}\), and in the case of new physics at scales \(\gg m_{W}\), they can be induced in matching out heavy fermion scalar operators of dimension six, as illustrated in Fig. 1, and given in Eq. (5). However, the dominant contribution of such scalar operators to \(\mu \to e\) conversion arises via the dipole or \((\bar{e}P_{L,R}\mu)GG\) operators. In Appendix A, we estimate the sensitivities of \(\mu \to e\gamma\) and \(\mu \to e\) conversion to scalar operators.

**ACKNOWLEDGMENTS**

We thank Jure Zupan and Lorenzo Calibbi for relevant comments on a first version of this manuscript. S. D. is happy to thank Vincenzo Cirigliano, Martin Gorbahn, Martin Hoferichter, Marc Knecht and Aneesh Manohar for useful communications. We thank the IN2P3 and KEK for funding FJPPL-TYL-HEP-06, which made this manuscript possible. This work was supported by JSPS KAKENHI Grants No. JP18H05231 (Y. K.), No. JP18H01210 (Y. U.), and No. 20H05852 (M. Y.). This work was partly supported by MEXT Joint Usage/Research Center on Mathematics and Theoretical Physics JPMXP0619217849.

**APPENDIX A: \(\bar{e}q FF\) IN THE RGEs**

In this Appendix, we briefly consider how a heavy new physics model could induce the dimension seven \(FF\) operators. Parenthetically, we notice a partial cancellation in the contribution of LFV Higgs interactions to \(\mu \to e\) conversion.

1. **Obtaining \(\bar{e}FF\) at \(\mathcal{O}(1/\Lambda_{\text{NP}}^2)\)**

   We assume that new physics generates dimension six CLFV operators at some scale \(\Lambda_{\text{NP}} > m_{W}\), which is high enough that dimension \(\geq 7\) operators can be neglected. Then \(\mathcal{O}_{FF,X}\) can be generated in matching out dimension six operators, such as a Higgs with flavor-changing couplings, or a flavor-changing scalar operator involving heavy fermions.

   We first consider the QED \(\times\) QCD invariant EFT below \(m_{W}\), in the notation of [34], where operators are added to the Lagrangian as \(\mathcal{L}_{SM} = \mathcal{L}_{SM} + 2\sqrt{2}G_{F}\Sigma C_{Lor, \nu}^{Lor, \nu}\), with \(\Sigma\) being flavor indices, and the subscript giving the Lorentz structure. As illustrated in Fig. 1, the scalar operators \(\mathcal{O}_{S,XX}^{\mu}, \mathcal{O}_{S,XY}^{\mu}\) [see Eq. (5)], match at \(m_{W}\) onto \(\mathcal{O}_{FF,X}\) and \(\mathcal{O}_{GG,X}\):

   \[
   \frac{C_{FF,X}}{v} = -\frac{\alpha Q_{\nu,\gamma}^{2} N_{\nu,\gamma}}{12\pi m_{\nu}} \left(C_{S,XX}^{\nu,\gamma} + C_{S,XY}^{\nu,\gamma}\right) \tag{A1}
   \]

   \[
   \frac{C_{GG,X}}{v} = -\frac{\alpha r_{Q,\gamma}^{2}}{24\pi m_{Q}} \left(C_{S,XX}^{\nu,\mu} + C_{S,XY}^{\nu,\mu}\right) \tag{A2}
   \]

   where \(Q \in \{c, b, t\}\). We focus on \(\psi \in \{\tau, c, b, t\}\) a heavy fermion, because the operators with \(\psi \in \{e, u, d, s\}\) contribute at tree level to \(\mu \to e\) conversion or \(\mu \to e\gamma\), and for \(\psi = \mu\), the operator contributes at one loop to \(\mu \to e\gamma\). It is interesting to pursue the loop effects of these heavy-fermion scalars, because the two heavy fermions make the operators difficult to probe directly in experiment.

   The \(\mathcal{O}_{S,XX}^{\mu}\) scalar operators (with the same chiral projector in both bilinears) contribute to the dipole operator via “Barr-Zee” diagrams. The \(\log^{2}\)-enhanced part is given by the one-loop RGEs of QED [35,36] as

   \[
   \Delta C_{D,X} \approx 8 \frac{\alpha_{e}^{2}}{e^{(4\pi)^{2}}} \left(C_{S,XX}^{\mu} m_{\tau} m_{W} m_{\mu} \ln^{2} m_{W} m_{\mu} + \frac{4m_{e}}{3m_{\mu}} C_{S,XX}^{\mu} m_{W}^{2} m_{\mu} \ln^{2} m_{W} m_{\mu} + \frac{m_{b}}{3m_{\mu}} C_{S,XX}^{b} m_{W} m_{\mu} \right) \tag{A3}
   \]
where \( C_{D,X} \) is the dipole coefficient at the experimental scale, and the coefficients on the right are evaluated at \( m_W \). Numerically, this is

\[
\Delta C_{D,X} \approx 9 \times 10^{-6} (245 C_{S,XX}^7 + 277 C_{S,XX}^8 + 117 C_{S,XX}^{10})
\]

where the current MEG bound \( \text{BR}(\mu \to e\gamma) \leq 4.2 \times 10^{-13} \) gives \( C_{D,X} \lesssim 10^{-8} \). Comparing to Eqs. (A2) and (26), one sees that the scalar quark coefficients \( C_{S,XX}^Q \) give contributions to \( \mu \to e\gamma \) conversion via the dipole and \( GG \) operators that are of the same order of magnitude and sign. So the SINDRUMII \( \mu \to e\gamma \) conversion bound has better sensitivity to these operators [34] than the current MEG bound. On the other hand, \( C_{S,XX}^\mu \) contributes principally to \( \mu \to e\gamma \) conversion via the dipole, rather than the \( FF \) operators, so high precision would be required to see the \( FF \) contribution, and MEG has better sensitivity.

The \( C_{S,XY}^{\mu \nu} \) operators can be Fierz-transformed to vector operators \(-\frac{1}{2}(e\rho_{\mu\nu})(\bar{q}P_{\mu}q)\), which contribute to \( \mu \to e\gamma \) at two-loop in EFT [36,37], that is \( O(a_s^2 \ln \Lambda) \):

\[
\Delta C_{D,X} \approx \frac{\alpha_s^2}{e(4\pi)^2} \left[ \frac{58}{9} C_{V,YY}^{\mu \nu} + \frac{116}{9} \sum_{l=e,\mu,\tau} C_{V,YY}^{l \nu} \right] + \frac{64}{9} (C_{V,YY}^{\mu \nu} + C_{V,YY}^{\nu \mu}) + \frac{22}{9} \sum_{q=d,s,b} C_{V,YY}^{qq} \\
- \frac{80}{9} (C_{V,XY}^{\mu \nu} + C_{V,XY}^{\nu \mu}) - \frac{14}{9} \sum_{q=d,s,b} C_{Q,XY}^{qq} \\
- \frac{50}{9} \sum_{l=e,\mu,\tau} C_{V,YY}^{l \nu} + 4 \sum_{f=b,c,s,t} C_{S,YY}^{f \nu} \frac{\alpha_s^2 N_f / m_f}{m_Y} \ln \frac{m_W}{m_Y} \\
(A4)
\]

where the logarithm should be inside the bracket, with a lower cutoff \( \sim m_b \to m_\mu \) which depends on the operator.

For the heavy quark coefficients \( C_{S,XY}^Q \), the contribution to \( \mu \to e\gamma \) conversion via the \( O_{GG,X} \) operator is clearly larger than via the dipole or \( O_{FF,X} \) [see Eqs. (A2), (26)], giving the SINDRUMII search the best sensitivity.

For the tau scalar coefficient, Eq. (A4) corresponds to \( \Delta C_{D,X} \approx 2.9 \times 10^{-4} C_{S,XX}^T \) which gives \( \mu \to e\gamma \) the current best sensitivity to this coefficient [34]. For \( \mu \to e \) conversion, this contribution to the dipole can be compared with \( \Delta C_{FF,X} \approx 0.019 C_{S,XX}^T \) from Eq. (A2). Equation (26) then implies that the contribution of \( C_{S,YY}^\mu \) to \( (\mu \to e\mu) \) via the dipole is an order of magnitude larger than via the \( FF \) operator, and a similar dominance of the dipole contribution arises in Aluminium. This can be understood diagrammatically, where both the contributions of \( C_{S,XY}^{\mu \nu} \) to the dipole, and to the scalar proton current, arise at 2-loop with a single log enhancement. However, the contributions to the dipole benefit from a \( m_\tau/m_\mu \) enhancement.

2. Of the sensitivity of \( \mu \to e\gamma \) conversion to flavor-changing Higgs interactions

The discussion so far has been in the context of QED × QCD invariant operators below the weak scale. However, since we assume \( \Lambda_{NP} \) is large, it is relevant to translate to the SMEFT, where SU(2) invariance restricts the operator basis to three scalar four-fermion operators at dimension six: the \( XX \) scalar for \( u \)-type quarks, and the \( XY \) scalars for \( d \)-type quarks and charged leptons. There is also a flavor-changing Higgs coupling, which matches onto \( O_{FF,X} \) and \( O_{GG,X} \) at the weak scale. Including also the dipoles, these operators appear in the SMEFT Lagrangian as

\[
\delta \mathcal{L}_{\text{SMEFT}} = \frac{1}{v^2} (C_{EH} H^\dagger H \tilde{H}_\mu H e + C_{EE} e_\nu (\tilde{e}_\tau H^\dagger H \sigma^\mu \epsilon e_\mu)) W_{\mu \nu} \\
+ C_{EB} e_\nu (\tilde{e}_\tau H^\dagger H \sigma^\mu e_\mu) B_{\mu \nu} + C_{LE} (\tilde{e}_\tau e_\mu \epsilon_{\tau r}) (\tilde{e}_r^\dagger e_\mu) \\
+ C_{LE} (\tilde{e}_\tau^\dagger e_\mu e_\tau) (\tilde{e}_r^\dagger e_\mu) \\
+ C_{LE} (\tilde{e}_\tau^\dagger e_\mu) (\bar{q}_B^\dagger u_A) \\
+ C_{LE} (\tilde{e}_\tau^\dagger e_\mu) (\bar{d}_A^\dagger q_B) + \text{H.c.}, \\
(A5)
\]

where the capitalized SU(2) indices are explicit when not contracted in the parentheses, \( \ell, q \) are doublets, \( u, d, e \) are singlets, flavor indices are superscripts, \( n \in \{c, t, b \} \), and the operator labels are according to [38]. The \( O_{EH} \) and \( O_{EB} \) will combine to the dipole, the \( O_{LE} \) operators Fierz to \( \mu \to e\gamma \) scalar operators with a \( \tau \) bilinear, and in the quark sector, \( O_{LE} \) is a \( YY \)-scalar operator (same chiral projector twice), whereas \( O_{LEQ} \) is \( XY \).

Loop effects between \( \Lambda_{NP} \) and the weak scale can be partially included via the RGEs of the SMEFT. Gauge boson loops can renormalize the coefficients, and mix the \( \epsilon_{\text{LEQ}} \) coefficients into the \( u \)-type tensor operator, and then to the dipole (as occurs below \( m_W \) for \( YY \) scalars). Higgs exchange can mix these scalars into vector four-fermion operators (to which there could be better experimental sensitivity), but for \( O_{\text{LEQ}} \) and \( O_{\text{LE}} \), this is negligible because suppressed by \( \sim y_\mu y_\gamma/(16\pi^2) \) \( (\psi \in \{\tau, b\}) \). We therefore suppose that the coefficients in Eq. (A5) are given at the weak scale \( m_W \), since the one-loop RGEs above \( m_W \) do not appear to significantly mix the \( YY \)-scalars into more experimentally accessible operators.

The coefficients from Eq. (A5) can be matched at \( m_W \) onto those of QED × QCD-invariant scalar four-fermion operators, relevant at low energy. All the scalar operators below \( m_W \) are generated at tree level, just that some arise due to Higgs exchange with a flavor-changing coupling from the \( O_{\text{HE}} \) operator, leading to correlations in the coefficients. One obtains [35]
The two-loop Barr-Zee diagrams involving top and W loops were included in the matching to the dipole, and the top loop matching the scalar operators onto \( FF \) and \( GG \) was included for these operators. These coefficients then run down to the experimental scale with the RGEs of QED \( \times \) QCD (see, e.g., [36]). QCD effects are numerically significant, although they only renormalize the coefficients.\(^5\) The scalar quark operators run like quark masses, and the operator \( \mathcal{O}_{GG,X} \) runs like the gluon kinetic term, which is accounted for by the wave function renormalization of the gluons. So the running parameters in the coefficient are evaluated at the matching scale.

Retaining only the contribution of the flavor-changing Higgs couplings, we obtain

\[
C_{D,R}^{\mu} \approx \left[ C_{\mu}^{\mu} + e\alpha s_{\gamma}^{2}/8\pi^{2}/y_{\mu}^{\gamma} \right] C_{\mu}^{\mu} \left[ 1 - \frac{4\alpha}{\pi} \ln \left( \frac{m_{\mu}}{m_{\mu}} \right) \right] + \cdots
\]

\[
C_{GG,R} = \frac{v^{2}}{12\pi m_{b}^{2}} C_{\mu}^{\mu} \left[ \frac{9}{3} + 1 \right] + \cdots
\]

where on the right appear SMEFT coefficients evaluated at \( m_{W} \), and the coefficients on the left can be input into the rate for \( \mu \rightarrow e \) conversion. Here \( C_{\mu}^{\mu} = C_{W}^{\mu}C_{\mu}^{\mu} - s_{W}C_{\mu}^{\mu} \).

Combining with Eq. (26), one sees that the contribution of the LFV Higgs interactions \( \mathcal{O}_{\mu}^{\mu} \) via \( \mathcal{O}_{GG,X} \) is of opposite sign and \( \frac{1}{3} \) the magnitude of the dipole contribution. The contribution via the light quark (\( u, d, s \)) scalar operators is slightly smaller than the \( GG \) contributions and of same sign, which worsens the sensitivity of \( \mu \rightarrow e \) conversion to \( \mathcal{O}_{\mu}^{\mu} \).\(^6\) Including both effects, \( \mu \alpha \rightarrow e \) cannot see

\[
C_{\mu}^{\mu} \leq 4.7 \times 10^{-5}
\]

whereas including only the dipole would give a sensitivity of \( \lesssim 1.6 \times 10^{-5} \).

**APPENDIX B: NUMERICAL VALUES OF OVERLAP INTEGRAL**

In Table III, we show the numerical values of \( F_{A} \), defined in Sec. III. A few nuclei are modeled by both the 2pF and 3pG distributions (14) [25], in which case we give the results with the latest distribution: 3pG for \( Z = 16, 28, 38, 40, 42, 50, 56, \) and 83, and 2pF for other nuclei.

---

\(^5\)QCD can also mix \( \mathcal{O}_{GG,X} \) to \( \mathcal{O}_{S,XX} + \mathcal{O}_{S,XX} \) by attaching the gluons to heavy quark line with a mass insertion. But we do not include this, because the scalar operators always have to be matched back to \( \mathcal{O}_{GG,X} \) in order to contribute to \( \mu \rightarrow e \) conversion.\(^6\)This cancellation is more effective for light targets like aluminium or titanium.
TABLE III. $F_A$ for each nucleus.
