Highlights

1. Ommochrome pigments in insects uniquely display red shift upon reduction
2. Color changes were modelled at quantum level using TDDFT
3. Electron-withdrawing auxochromes affect optical properties only in reduced states
4. Electronic couplings that facilitate charge-transfer transitions drive red shifts
5. Larger red shifts are associated to higher antiradical behavior in reduced states

Graphical Abstract

Abstract

In the colorful world of pigments and dyes, the chemical reduction of chromophores usually leads to bleaching because of π -conjugation interruption. Yet, the natural phenoxazinone-based ommochrome pigment called xanthommatin displays a bathochromic (i.e. red) shift upon two-electron reduction to its corresponding phenoxazine, whose electronic origins are not completely disclosed. In this study, we investigated, at quantum chemical level, a series of phenoxazinone/phenoxazine pairs that was previously explored by UV-Vis spectroscopy (Schäfer and Geyer, 1972), and which displays different hypsochromic and bathochromic shifts upon reduction. Density Functional Theory (DFT) and Time-Dependent DFT (TDDFT) have been applied to compute their optical properties in order to find a rational explanation of the observed photophysical behavior. Based on our results, we propose that the electro-accepting power of auxochromes and their conjugation facilitate intramolecular charge-transfers across the phenoxazine bridge by lowering unoccupied molecular orbitals via electronic and geometric couplings, leading ultimately to bathochromy. Our findings therefore suggest new potential ways to adjust the color-changing ability of phenoxazinones in technological contexts. Overall, this model extends our mechanistic understanding of the many biological functions of ommochromes in invertebrates, from tunable color changes to antiradical behaviors.

Keywords: Antiradical, Bathochromy, Insect pigment, Ommochrome, Phenoxazine, Time-Dependent Density Functional Theory

1. Introduction

Chemical colors in animals are mostly produced by π -conjugated organic molecules, which contain a chromophore with alternating single and double bonds. Extending the electronic conjugation of chromophores usually leads to bathochromic shifts (i.e. absorption at longer wavelengths), while breaking the π -system induces hypsochromic shifts (i.e. absorption at shorter wavelengths) [1,2]. Therefore, even limited chemical reduction of organic dyes and pigments can result in their bleaching due to the saturation of double bonds [1]. However, one class of biological pigments –the phenoxazinone-based ommochromes– has appeared to be an exception to this rule [3]. Xanthommatin, the best-known and most-widespread ommochrome, is yellow in its oxidized state (oxo-pyrido[3,2-*a*]phenoxazinone; absorption at 440 nm) but red when reduced to dihydroxanthommatin (oxo-pyrido[3,2-*a*]hydroxyphenoxazine; absorption at 480 nm) [3]. This unusual color-changing molecular property mediates important biological functions [4], such as nuptial colorations in dragonflies [5], light filtering in insect eyes [6], as well as electron transfers in a marine worm [7,8] and various insects [9–11]. Besides, the bathochromic reduction of xanthommatin has shown biomimetic potential to craft color-changing electrochromic devices [12]. Thus, unraveling the chemical origin of this distinct bathochromic reduction may have implications for both biologists and material scientists.

In 1972, Schäfer and Geyer synthesized a series of bathochromic and hypsochromic phenoxazinone/phenoxazine pairs to mimic ommochromes, and analyzed them by UV-Vis spectroscopy [13]. They showed that only 1-acetyl-2-[amino/hydroxy]-phenoxazin-3-ones (see Figure 1 for the numbering of phenoxazinones) underwent bathochromic reduction. They concluded that this bathochromic shift was due to an increased resonance in the molecular reduced states, in relation to the dipolar structure of the 1-acetyl auxochrome [4,13]. Unfortunately, after this pioneering experimental study, the model proposed was never further validated, nor rationalized making use of quantum chemical approaches. Yet, understanding the correlation between geometrical and electronic molecular structures with chromatic shifts in phenoxazinonic dyes and pigments hold great promises to further unravel their natural functions and technological uses.

The recent advances in quantum chemical methods for the description of ground and excited electronic states has greatly helped to rationalize and to predict the optical properties of molecules, especially in the case of organic dyes [14,15]. In particular, the advent of Density Functional Theory (DFT) and Time-Dependent DFT (TDDFT), together with an increased availability of computational resources, has enabled to successfully model a vast number of biochromes, pigments and dyes (see for instance references [16–18]). Because of its favorable

cost-to-accuracy ratio, we selected TDDFT to investigate the properties of phenoxazinone/phenoxazine pairs firstly to test the validity of Schäfer and Geyer's model and then to rationalize the link between the structure and photophysical properties of ommochromes. However, since TDDFT performances may quantitatively depend on the exchange correlation functional used [15,19], a preliminary benchmark of commonly applied functionals has been performed on both phenoxazinones and phenoxazines. In particular, we tested a set of global hybrid functionals with various percentages of exact exchange, as well as range-separated hybrids (RSH), which usually perform better for excited states with a substantial amount of non-local charge transfer (CT). Once the computational approach set, several structural (e.g. planarity) and electronic properties (e.g. aromaticity indexes and CT character) were analyzed to establish the structure-property relationship of chromic shifts upon reduction. By applying the same techniques to ommochromes and resorufin, an important hypsochromic biotechnological dye, we rationalized their color-changing behavior upon reduction in terms of electronic and geometric couplings in the reduced phenoxazine state. Finally, our electronic model of ommochromes provides a mechanistic understanding of their unique optical properties, which helps rationalizing their widespread and various uses in invertebrates, as well as in new biomimetic applications.

2. Computational Details

2.1 Computational Approaches and Benchmarks

All quantum chemical calculations were performed with the Gaussian program [20] at the DFT level [21] while molecular orbitals were visualized using the Gabedit program [22].

The B3LYP functional [23] was used to locate minima since it generally provides reliable geometric parameters for organic compounds [24], while Grimme's dispersion correction using the D3(BJ) model [25,26] was also introduced to account for weak interactions. Bulk solvent effects were considered using the COSMO approach to polarizable continuum models (CPCM) [27]. Different solvents were considered depending on experimental conditions [4,13,28], as specified in Supporting Information (SI).

Each structural optimization was followed by a harmonic frequency calculation, ensuring that all computed vibrational frequencies were positive, as they should be for an energy minimum on the potential energy surface. The optimized coordinates of all investigated compounds investigated are listed in SI. The 6-311G(d,p) basis set was chosen for all structural optimizations, after a careful test (see SI for details).

Using these molecular structures optimized at the identified theoretical level (B3LYP-D3(BJ)/6-311G(d,p), vertical absorption energies (ΔE^{vert}) were then computed within the linear response Time-Dependent DFT (TDDFT) framework [29] using the non-equilibrium approximation of CPCM [27]. It is well known that the computed electronic adsorption energies depend on the chosen DFT approach. While some general trends appear from previous detailed benchmarks [19,30], it is a better practice to verify the performances on the systems under investigations. To this end, as functionals based on local-density (LDA) and generalized gradient approximation (GGA) are known to perform poorly for the calculation of vertical excited states [30], TDDFT calculations were carried out only considering 12 functionals, chosen among the most representative (see SI for details)

All 18 phenoxazinone/phenoxazine pairs depicted in Fig 1 were used for this TDDFT benchmark, while the experimental values were taken from reference [13]. If a compound in this dataset showed broad/unresolved absorbance peaks, the one with the highest wavelength was systematically used. The performance of the selected functionals was evaluated using the following criteria: mean absolute errors (MAE) on ΔE^{vert} (target to be below 0.2 eV), comparable errors for both phenoxazinones ($\Delta E^{\text{vert}}_{\text{ox}}$) and phenoxazines ($\Delta E^{\text{vert}}_{\text{red}}$), MAE on chromic shifts (defined as $\Delta E^{\text{vert}}_{\text{shift}} = \Delta E^{\text{vert}}_{\text{red}} - \Delta E^{\text{vert}}_{\text{ox}}$; target to be below 0.2 eV), comparable errors for both bathochromic and hypsochromic redox pairs, high correlations with experimental values for both absorption energies and chromic shifts, and high number of well-predicted chromic shifts.

Based on this benchmark, whose results are reported and commented in the SI, the M05 functional [31] results as the best compromise and the most reliable functional for predicting the chromic reduction of phenoxazinones to phenoxazines.

Following previous experience [32] and the test carried out for the 2-amino-7-hydroxy-phenoxazin-3-one molecule (see SI for details), all the vertical transition energies were computed using the 6-31+G(d) basis set.

2.2 Computation of Descriptors

Several descriptors were considered in order to assess the relationship between the structural and electronic parameters of the considered dyes and their optical behavior.

The Harmonic oscillator model of aromaticity for heterocycle electron delocalization (HOMHED) is a geometric index of aromaticity that evaluates bond conjugation by comparing bond lengths of a compound to those of an ideal aromatic compound [33]. The closer to 1

HOMHED is, the more conjugated, and thus aromatic, the compound is. The HOMED values were computed using the Gabedit program and the parameters described in reference [33].

Another commonly applied index is the so-called nucleus-independent chemical shifts (NICS) which is based on the deshielding induced at a center of an aromatic ring by the ring current [34]. The more deshielded NICS is, the more aromatic the compound. The NICS indexes were computed at the center of each ring (NICS(0)) using the above mentioned level of theory and the gauge-including atomic orbital (GIAO) method [35].

The third descriptor is the charge-transfer distance (D_{CT}) that evaluates the hole-electron mean distance associated to an electronic excitation, thus unraveling its nature (local or charge transfer). It is easily computed measuring the distance between the barycenters of charge distributions corresponding to a density depletion and a density increase upon excitation [36].

Finally, some descriptors, issued from the so-called conceptual DFT [37], were also considered, including electron affinity (EA), hardness (η) and electro-accepting power (ω^+). The latter measures the local charge-acceptance of a compound and thus its capacity to accept fractions of electron during charge-transfer phenomena [38,39].

3. Results

A total of 15 molecular pairs from Schäfer and Geyer's series [13] were considered for a detailed analysis (see SI for the explanation on this choice). Electronic and geometric properties of the bathochromic ommochrome pair xanthommatin/dihydroxanthommatin and the hypsochromic dye pair resorufin/dihydroresorufin were also investigated for sake of completeness. Experimental UV-Visible data for these molecules were taken from references [3] and [40], respectively.

3.1 Schäfer and Geyer's Phenoxazine Series

Nearly 50 years ago, Schäfer and Geyer proposed that the bathochromic shifts of some substituted phenoxazinones upon reduction could be related to an increase of resonance forms [13], and thus to a greater conjugation of the phenoxazine chromophore. To test this hypothesis, we computed two indices that can be related to the degree of delocalization and aromaticity in a molecule, namely the HOMHED and NICS(0) indexes [37].

The HOMHED index basically considers computed structural parameters, namely related to bond length alternation between single and double bonds, to evaluate the degree of electron delocalization, as detailed in the computational section. This index has been evaluated for two possible delocalization patterns in the molecule as highlighted in Figure 2A and Figure

S7 namely: i) the pattern involving delocalization along ring C (cHOMHED, Fig 2A) and ii) the delocalization pattern along all bonds involved in the resonant forms produced by substituents in position 1, 2 and the phenoxazine nitrogen (sHOMHED, Fig S7). In contrast with the experimental hypothesis, no clear correlation with chromic shifts can be drawn in the case of the sHOMHED pathway (Fig S7) while, in the case of the cHOMHED index, a partial positive correlation ($R^2 = 0.77$) can be found (Fig 2B). According to this index, hypsochromicity is associated with an increase in aromaticity of ring C. This partial correlation is nonetheless lost when considering the NICS(0) index, an index based on electronic properties. While considering only bathochromic pairs (Fig 2C), a positive correlation between aromaticity and bathochromicity can be found ($R^2_{\text{batho}} = 0.79$), in agreement with the experimental hypothesis, no correlation can be found if both batho and hypsochromic pairs are considered. Indeed three hypsochromic phenoxazines show the lowest NICS(0) and thus the highest aromaticity. In short, these two measures of the aromaticity, which are different in nature (electronic and structural origin), do not support the hypothesis of Schäfer and Geyer on the observed color change of ommochromes and, particularly on the different batho and hypsochromic behavior.

In order to have a general picture of these behaviors and to propose a more general rationalization of the chromic reduction of phenoxazinones to phenoxazines, we analyzed the general trends arising from the mean values and dispersion of the set of structural and electronic parameters chosen, as reported in Table 1.

First, we note a significant structural difference between phenoxazines and phenoxazinones, the first being sizably less planar than the latter ($+11.5^\circ$; Table 1), in agreement with the expected sp^3 configuration of the phenoxazine nitrogen. Consistently, in average, both the cHOMHED and the NICS(0) indicate an increased aromaticity in the reduced systems (Table 1). Nonetheless, no correlation between chromicity and structural parameters can be directly established.

At the ground electronic state (GS), reduction leads to the destabilization of both the highest occupied molecular orbital (HOMO, +1.47 eV) and the lowest unoccupied molecular orbital (LUMO, +1.7 eV; Table 1). The HOMO-LUMO gap is only slightly higher in phenoxazines (+0.23 eV) but the spreading of values for these systems is computed to be three times larger than for phenoxazinones (Table 1), thus indicating that phenoxazines present both significantly lower and higher HOMO-LUMO gaps than phenoxazinones. This pattern is mirrored by those of ΔE^{vert} and ΔE^{exp} , consistently with the presence of batho and hypsochromic pairs. Looking at properties involving excited states, reduction leads to oscillator strengths and

transition dipole moments more than twice lower than in phenoxazinones (Table 1). These data are in agreement with the hypochromic shift (i.e. less intense absorption) observed upon reduction to phenoxazines [13]. Finally, dipole moments and, consistently, the charge-transfer distances (D_{CT}) associated to excited states are computed to be higher in phenoxazines (+4.06 D and +0.9 Å, respectively; Table 1). This latter finding indicates a larger intramolecular charge transfer (ICT) character associated to electronic transitions in phenoxazines than in phenoxazinones.

More interestingly, we note that dispersion of the values associated to most of the electronic and structural parameters is greatly larger in phenoxazines (Table 1 and Fig 3A). Therefore, we can formulate the hypothesis that different chromic shifts are essentially driven by differences in the reduced systems independently of the corresponding oxidized ones. Consistently to this hypothesis, chromic shifts show a relatively strong linear correlation ($R^2 = 0.84$) with ΔE_{red}^{vert} (Fig 3B) but no correlation at all with ΔE_{ox}^{vert} (Fig S8). In line with these results, there is a clear distinction between ΔE_{red}^{vert} of bathochromic and hypsochromic compounds, while ΔE_{ox}^{vert} do not significantly differ (Fig 3A).

To further validate the hypothesis that chromicity is mainly linked to properties of the reduced forms, the electronic properties of four representative pairs, including two bathochromic (**1** and **2**) and two hypsochromic phenoxazines (**14** and **15**), were considered (Fig S9). In all cases, since the π - π^* excited states of interest have a dominant HOMO-LUMO character for both oxidized and reduced compounds, energies of the HOMO and LUMO were firstly analyzed. Consistently with the results presented in Table 1, only the molecular orbital energies of the reduced compounds vary consistently with chromic shifts (Fig S10). Furthermore, the range of HOMO-LUMO gap values in phenoxazines is primarily associated to a wider variation in LUMO than in HOMO energies (Table 1 and Fig S10).

All these data suggest that a simple correlation could link chromic shifts to LUMO energies of reduced phenoxazines, which are *in fine* directly related to their electron affinity (EA) and thus to their reactivity and antiradical properties [41,42]. Indeed, a clear correlation is found between computed chromic shift and electron affinity of phenoxazines (EA_{red} , Fig 4A; $R^2 = 0.61$). This correlation is further improved by considering chemical hardness in the reduced states (η_{red} , Fig 4B; $R^2 = 0.82$), which implicitly takes into account also the variation of the energy of the HOMO level.

Since LUMOs energies can be tuned by the presence of electron-withdrawing auxochromic groups (EWA) [43], we computed the frontier orbital energies of the different

EWA that can be placed in positions 1 and 8 (Fig 1). Consistently with our hypothesis, the two EWA (i.e. acetyl and γ -oxobutenyl) with the lowest LUMO energies and highest electro-accepting powers, ω^+ , are associated to bathochromic shifts, while EWA with high LUMO energies (such as cyano or carboxy substituted) induce hypsochromic shifts (Table 2). Of note, the *tert*.butyl-carbonyl EWA shows a hypsochromic shift whereas its LUMO energy is close to that of acetyl. This result indicates that other parameters than the LUMO stabilization may play a role in the observed shifts. In particular, *tert*.butyl-carbonyl is a bulky EWA compared to acetyl and carbomethoxy. In this case, as already proposed by Schäfer and Geyer, steric hindrance can alter excitation energies by constraining the carbonyl out-of-plane [13]. Such an effect is observed in the case of compound **14r** for which a large dihedral angle between ring C and carbonyl in position 1 is computed (59° in **14r** vs 8° in **1r**) (Fig S11). To test whether this torsion destabilized the LUMO and thereby induced the hypsochromic shift, we computed the ΔE^{vert} as a function of the torsional angle for compounds **1r**, **14r** and **15r** (Fig 5A). The results show that for dihedral angles greater than 30° there is a significant hypsochromic effect, with the maximum hypsochromy obtained around 90° (from 0.30 eV for **1r** to 0.83 eV for **15r**; Fig 5A). Below 60° , **14r** becomes less hypsochromic than **15r** in its optimized geometry (Fig 5A), in agreement with the lower LUMO energy of *tert*.butyl-carbonyl compared to carbomethoxy (Table 2). However, **14r** can never reach the bathochromicity of **1r**, even at angles near 0° (Fig 5A). These results indicate that the steric hindrance of *tert*.butyl-carbonyl explains, partly at least, the hypsochromicity of **14r**.

Next, we considered model systems obtained by functionalization of the 2-hydroxy-phenoxazin-3-one/2,3-dimethoxy-phenoxazine pairs with EWA with either stabilized (nitro) or destabilized (carboxamide) LUMOs (Table S1 and Fig 5B-C). All substituents were placed in position 1 and forced to lie within ring C plane after geometrical optimization to avoid torsion of molecular orbitals due to steric hindrance. The results show that LUMO energies of substituents explain 95 % of the variation in chromic shifts upon reduction (Fig 5B). They also confirm that increasing the electro-accepting power of substituents in position 1 leads to more bathochromic phenoxazines (Fig 5B-C and Table S1).

3.2 Application to Ommochromes and Other Phenoxazinone Dyes

Chromic shifts of two other important pairs of natural and technological relevance were next considered, namely xanthommatin/dihydroxanthommatin (bathochromic invertebrate pigments) and resorufin/dihydroresorufin (hypsochromic biotechnological dyes; see Figure 6 and Table S2).

The 8-substituted-oxo-pyrido[3,2-*a*]phenoxazin-3-one xanthommatin presents HOMO (-6.89 eV) and LUMO (-3.35 eV) energies very close to the mean HOMO and LUMO energies of the phenoxazinones investigated above (compare Fig 6 with Table 1 and Fig S9). The corresponding reduced 8-substituted-oxo-pyrido[3,2-*a*]-3-hydroxy-phenoxazine dihydroxanthommatin possesses not only a highly stabilized LUMO (-2.02 eV), but also a relatively stabilized LUMO+1 (-1.59 eV). Overall, the molecular orbitals of xanthommatin and dihydroxanthommatin resemble those of the phenoxazinones and phenoxazines described above both qualitatively and quantitatively (Fig 6 and Fig S9), which indicates that the effect of EWA on the reduced state should also control their chromic shifts. The substituent in position 8 if ommochromes is closely related to acetyl, while the oxo-pyrido ring attached on positions 1 and 2 resembles γ -oxo-butenyl. The two corresponding carbonyl functions lie within ring A and C planes, respectively. All these characteristics predicted a bathochromic shift upon reduction. Accordingly, the molecular orbital gaps of dihydroxanthommatin are 3.21 eV (HOMO-LUMO) and 3.64 eV (HOMO-L+1), thus they lie within, and even beyond, the range of bathochromic transitions already investigated in this study (Table 1). In addition, dihydroxanthommatin hardness is the lowest we computed (Table S2 and Table 1). Excited state computations consistently predict two bathochromically shifted electronic transitions, which involve a HOMO-LUMO and a HOMO-L+1 transitions, respectively (Table S2). Both transitions are characterized by a significant ICT (Table S1 and Fig 6). The first excited state (S1) is less intense than the second (S2) and their ΔE^{vert} bracket the experimental value ($\Delta E_{S1}^{\text{vert}} = 2.25 \text{ eV} < \Delta E^{\text{exp}} = 2.58 \text{ eV} < \Delta E_{S2}^{\text{vert}} = 2.69 \text{ eV}$), which corresponds to the maximum of a broad absorption peak [4].

On the contrary, the resorufin/dihydroresorufin pair presents all the characteristics associated to hypsochromic shifts: the absence of EWA, a small HOMO-LUMO gap in the oxidized state, a highly destabilized LUMO and high chemical hardness (Fig 6 and Table S2). Accordingly, TD-M05 calculations predict a highly hypsochromic shift upon reduction (1.05 eV; Table S2). To the best of our knowledge, the exact experimental absorbance of dihydroresorufin has never been reported in the literature, but resorufin is known to lose its color upon reduction [28], which is in agreement with our calculations.

4. Discussion

The above reported results clearly show that the model originally proposed by Schäfer and Geyer to explain the experimentally observed chromic shifts in substituted phenoxazinone/phenoxazine pairs, which correlates bathochromic shifts to an increase in

resonance structures [13], is unable to explain qualitatively why 1-acetyl-phenoxazines are bathochromic and why the closely-related 1-carbomethoxy-phenoxazines are hypsochromic. Our analysis, based on modern descriptors of aromaticity, invalidates the general applicability of this model, showing that there is no clear correlation between descriptors of aromaticity and bond conjugation with color changes upon reduction. On the other hand, it appears that bathochromic and hypsochromic shifts correlate well with electronic properties of reduced forms, in particular with all descriptors containing information on the strength and nature of the EWA present in the molecule, such as LUMO energy, electro-accepting power and EA.

On this basis, to explain the color-changing behavior of substituted phenoxazinones upon reduction, we propose the following structure-property model. (Fig 7). The bright excited state of phenoxazinones (i.e. oxidized forms) that is responsible for the yellow-orange color of this chromophore is of Locally Excited (LE) character stemming from a π - π^* transition. This transition is not particularly affected by EWA in position 1, explaining why excitation energies of substituted phenoxazinones do not vary significantly as a function of the EWA. Therefore, the energy of this LE state in phenoxazinones defines a common reference for bathochromy and hypsochromy of substituted phenoxazines (Fig 7B). The 3-hydroxy-phenoxazine chromophore (i.e the reduced form of the pair) is on the other hand characterized by a bright excited state displaying a partial intramolecular CT (ICT) character (Fig 7A). When 3-hydroxy-phenoxazine is substituted in position 1 with a EWA, the EWA LUMO hybridizes with the phenoxazine UMOs and stabilizes them, thus lowering the energy of ICT. The strength of stabilization depends primarily on two factors (Fig 7A): (1) an electronic one that is the energy of EWA LUMO and (2) a structural one that is the magnitude of the dihedral angle formed by the EWA with the corresponding phenoxazine ring ruling its conjugation.

First, EWAs with high (low) electro-accepting powers stabilize (destabilize) the corresponding substituted phenoxazine UMOs, which decreases (increases) their excitation energies and leads to bathochromic (hypsochromic) shifts upon reduction (Fig 7B). This translates into ICT associated to lower (higher) energies, hence into red (yellow)-shifted colors (Fig 7B). This mechanism explains why acetyl and carbomethoxy induced bathochromic and hypsochromic shifts, respectively.

Second, from a structural viewpoint, when a substituent in position 1 is coplanar with the phenoxazine ring, the (L)UMOs are fully conjugated and thus highly stabilized. Structural decoupling decreases this effect (Fig 7B) explaining why sterically hindered EWA, despite having a high electro-accepting power can indeed induce hypsochromic shifts, as in the case of the *tert*.butyl-carbonyl. The same applies for the methylated phenoxazine nitrogen that induced

a hypsochromic shift because of steric hindrance with the acetyl in position 1, as already proposed by Schäfer and Geyer [13]. Overall, we propose that electronic and geometric interactions of EWA with the phenoxazine UMOs produce a wide range of ICT energies, which ultimately leads to a continuous hypso-to-bathochromic scale (Fig 7B).

Note that this model can be refined in several ways. For example, we could take into account the effect of electron-donating auxochromes (EDA) on the phenoxazine HOMO. This would explain why HOMO-LUMO gaps, rather than LUMO alone, better predicted chromic shifts in the complete set of investigated compounds (in which EDA in position 2 varies). We could also add the effect of EWA in other positions than 1. From the investigated compounds, it appears that EWA at position 5, 6, 7 and 8 have an effect on the phenoxazinone LUMO too, which (slightly) modifies the threshold for bathochromy. Most interestingly, EWA in position 8 could interact with the EWA in position 1 either synergistically (both EWA are similar and stabilize the same ICT, see **8r**), additively (different bathochromic EWA stabilize two different ICT, see dihydroxanthommatin) or antagonistically (hypsochromic and bathochromic EWA lead to ICT not stabilized enough, see **9r**). Note that for pair **9** TD-M05 calculations could not predict the correct color-changing behavior upon reduction. This indicates that other parameters not modelled in this study, such as direct solvent interactions [16], could also finely tune the color-changing effect of reduction.

Of note, the structure-to-property relation found here has also implication for the reactivity of these compounds. Indeed, HOMO-LUMO gap and LUMO energy are known to be directly related to hardness and electron affinity, respectively, which define some aspects of the chemical reactivity of a compound [39]. Our calculations showed that those two chemical parameters were highly correlated with the direction of chromic shift. We conclude that the softer and the more electrophilic a phenoxazine is, the more bathochromic and antiradical it becomes.

5. Conclusions

In this study, we unraveled the electronic mechanisms behind the atypical bathochromic (i.e. red shift) reduction of ommochrome pigments in invertebrates, particularly at play in the ecologically important nuptial coloration of dragonflies [5]. We established the relation between the nature and strength of electron-withdrawing auxochromes (EWA) that rules the magnitude of the phenoxazine intramolecular charge-transfer and the observed chromic shift. Other parameters, such as the angle formed by EWA with the attached phenoxazine ring, tune the direction of the chromic shift upon reduction.

From a technological viewpoint, crafting phenoxazines with new EWAs that allow a wider range of chromic shifts than currently available [12] might foster the field of ommochrome-based electro-chromic devices. The influence of EWA conjugation on chromic shifts suggests that these devices could be made even more flexible by dynamically altering the torsion angle of EWAs, for example through tunable interactions with the coated surface.

From a biological viewpoint, it is well established that optical properties and chemical behaviors are both important functions of pigments [1,44–46]. By linking together those two functions through EWA properties, our study suggests that invertebrates may have favored bathochromic ommochromes because of both their better capacity to protect cells against reactive species in the reduced state, as previously suggested [42], and their tunable red shift, which we discuss in two biological situations. First, the occurrence of a decarboxylated form of xanthommatin can be explained by its decarboxylated EWA producing a less bathochromic reduced state. It could therefore allow a wider range of colorations than with xanthommatin alone, as seen in cephalopods [47]. Second, it has long been known that absorbance spectra of ommochromes are red-shifted in insects eyes compared to *in vitro* ([6,48,49]). We propose that properties of the matrix in which ommochromes are deposited and that alter their absorbance, such as proteins [49,50] and metals [51,52], do so by modulating the electrophilicity and the conjugation of ommochrome EWAs, leading ultimately to their bathochromic behaviors uniquely observed *in vivo*.

In conclusion, our study reinforces the idea that the unique electronic properties of ommochromes make them a powerful technological and biological framework to tune rapidly and efficiently color-changing materials.

Acknowledgments

We are grateful to Alistar Ottochian, Michele Turelli and Bernardino Tirri for their technical support. F.F. thanks the ENS de Lyon for financial support. I.C. gratefully acknowledges support from the European Research Council (ERC) for funding under the European Union's Horizon 2020 research and innovation program (grant agreement No 648558, STRIGES CoG grant). This work formed part of the doctoral dissertation of F.F. under the supervision of J.C.

Tables

Table 1. Average values and dispersion of electronic and structural parameters computed for oxidized phenoxazinones and reduced phenoxazines.

	Phenoxazinone (mean $\pm$ SD)	Phenoxazine (mean $\pm$ SD)
ΔE^{exp} (eV) ^a	2,80 $\pm$ 0,10	2,91 $\pm$ 0,20
ΔE^{vert} (eV)	2,71 $\pm$ 0,09	2,75 $\pm$ 0,23
Phenoxazinone/Phenoxazine dihedral angle ($^{\circ}$)	0,6 $\pm$ 0,3	12,0 $\pm$ 5,9
HOMO energy (eV)	-6,84 $\pm$ 0,14	-5,37 $\pm$ 0,10
LUMO energy (eV)	-3,34 $\pm$ 0,13	-1,64 $\pm$ 0,25
HOMO-LUMO gap (eV)	3,50 $\pm$ 0,08	3,73 $\pm$ 0,26
Oscillator strength	0,83 $\pm$ 0,21	0,40 $\pm$ 0,15
Transition dipole moment (D)	12,45 $\pm$ 3,41	5,85 $\pm$ 2,58
Dipole moment of GS (D)	6,34 $\pm$ 1,98	6,52 $\pm$ 2,56
Dipole moment of ES (D)	8,29 $\pm$ 2,70	12,35 $\pm$ 4,19
NICS(0) of ring C (ppm)	-0,87 $\pm$ 0,64	-8,77 $\pm$ 0,54
cHOMHED of ring C	0,65 $\pm$ 0,05	0,97 $\pm$ 0,01
D_{CT} ($\text{\AA}$)	1,71 $\pm$ 0,30	2,61 $\pm$ 0,60

^a Experimental values are taken from reference [13]

Table 2. Computed chemical descriptors (in eV) of electron-withdrawing auxochromes (EWA) in relation with the chromic shifts they induce experimentally in phenoxazinone/phenoxazine pairs.

EWA	HOMO	LUMO	H-L gap	ω^+
<i>bathochromic shifts</i>				
Acetyl	-7.64	-0.59	7.06	1.01
γ -oxo-butenyl	-7.56	-1.59	5.97	2.05
<i>hypsochromic shifts</i>				
Carbomethoxy	-8.59	0.01	8.60	0.72
Cyano	-10.61	0.32	10.93	0.74
<i>tert.</i> butyl-carbonyl	-7.42	-0.57	6.85	0.98
