The synthesis of a copolymer derived from poly(3-hexylthiophene), one of the monomers bearing an aniline group, is described. Like the homopolymer, this copolymer is able to functionalize carbon nanotubes by π -stacking of the thiophene units onto the hexagonal network of the nanotubes. It can as well be covalently attached onto carbon nanotubes walls without the need of an intermediate chemical step. While the dispersion of the non-covalent nanohybrids in THF is stable for few hours only, the one of the covalent nanohybrids is stable for weeks, showing the efficiency of the functionalization. The comparison between spectroscopic characterizations of both covalent and non-covalent systems shows that the copolymer organizes differently at the interface with the nanotubes in each case, in agreement with the effectiveness of the reaction of addition.

KEYWORDS: Poly(3-hexylthiophene) derivative, Single Wall Carbon Nanotubes, covalent functionalization, Optical Absorption, Photoluminescence, Raman Spectroscopy

INTRODUCTION

Much work dealing with covalent and non-covalent functionalization of carbon nanotubes by conjugated polymers, among them poly(3-hexylthiophene) (P3HT), has been performed in order to elaborate new nanohybrids, in the solid state or in solution. In the case of covalent nanohybrids, single-wall carbon nanotubes (SWNTs) are firstly oxidized¹⁻⁴ or reacted with a small molecule such as 4-substituted anilines.^{5,6} A polymer can be grafted onto or from the resulting side groups. This two steps route makes difficult to predict an estimate of the functionalization rate and renders identical experiments difficult to compare.

In the present work, we report an alternative route by designing and synthesizing a statistical copolymer derived from P3HT able to be grafted directly onto SWNTs by the side chains. We chose a low ratio of reactive to non-reactive comonomers in order to prevent too strong modifications of the structure of the SWNTs.⁷ This route may lead to nanohybrids with peculiar optical properties such as the brightening of SWNTs photoluminescence.^{8,9}

Using this copolymer, we first functionalized SWNTs non-covalently in order to get the most dispersed suspension of functionalized isolated nanotubes (hereafter called non-covalent nanohybrid); then we used such suspensions to functionalize them covalently in situ (hereafter called covalent nanohybrid). The stability of the resulting suspensions and the comparison between the physico-chemical properties of both nanohybrids show that the nanotube-copolymer interfaces in both systems are drastically different, as are the interchain interactions, in agreement with the effectiveness of the covalent functionalization.

RESULTS AND DISCUSSION

The copolymers we targeted have a P3HT backbone where some of the side chains are functionalized with aniline groups at their end (Scheme 1). The aniline group can react with the SWNTs by Tour's reaction:¹⁰ the aniline is converted in situ to its diazonium, which alkylates the SWNTs.

Scheme 1. Synthesis of the reactive copolymer.

The targeted polymers were synthesized by GRIM polymerization, developed by the groups of McCullough¹¹ and Yokozawa¹², and proved to reach quasi-control and good regioregularity. Alkylthiophene monomers bearing a bromine at the end of the side chains have been successfully polymerized by this method, showing that no side reaction occurs at the bromide of the side chains.¹³ GRIM copolymerization of 3-alkylthiophenes with close structures have been shown to yield random copolymers.¹⁴ We have copolymerized the 5-iodo 2-bromo monomers **1** and **2**. Their structures differ only by the bromine on the end of side chain. We fixed the molar proportion of **2** at 15%. This ratio has been chosen to avoid a too strong alteration of the nanotubes structure after their functionalization. It should lead at maximum to a few covalent links per thousand SWNT carbon atoms. Before the polymerization itself, **1** and **2** are metallated by the exchange of iodine with *i*-PrMgCl to yield the monomers **1'** and **2'**. We have measured the conversion rate of this step by the method of Catala.¹⁵ after metallation, an aliquot of the solution was quenched with CD₃OD and observed

by NMR. The hydrolysis of **1** and **2** forms the corresponding compounds deuterated in 5, identified by a singlet at 6.78 ppm. Beside this major compound, the NMR spectra also show unreacted **1** or **2** (singlet at 6.95 ppm), and 3-alkyl-2-bromothiophene (doublet at 7.17 ppm) coming from the hydrolysis of **1** or **2** by protonated impurities in the reaction medium (Figure S1, Supporting Information). This analysis provides the rate of active monomer (ca 90 %), and the required amount of catalyst for the targeted degree of polymerization. It also proves that the bromide on the side chain is not affected by the organomagnesium and that metallation takes place only at position 5.

The polymerization was achieved by addition of the catalyst and followed by UV-vis. It yielded the brominated copolymer (copolymer **A** in Scheme 1) with an average mass M_n of 36000 g mol⁻¹ (5200 g mol⁻¹) and a dispersity of 1.41 (1.12). The fraction of side bromide was derived from the ratio of the integrals of the peaks of the vicinal protons of Br (triplet at 3.43 ppm) to those of the α -methylene (multiplet at 2.81 ppm) and was estimated to 15 $\pm$ 2% for M_n of 36000 g mol⁻¹ (14 $\pm$ 2% for M_n of 5200 g mol⁻¹), in register with the feed ratio Table 1).

Table 1. Characteristics of the copolymers **A**

Copolymer	M_n [g mol ⁻¹] ^{a)}	$\bar{D}$	Rate of Br-hexyl [%] ^{b)}
A 5000	5200	1.1	14 $\pm$ 2
A 36000	36000	1.41	15 $\pm$ 2

^{a)} determined by SEC-MALS (Figure S2, Supporting Information); ^{b)} determined by NMR

The regioregularity of the copolymer was estimated by comparing the intensity of the signals of the proton 4 of the thiophene, according to the assignment of the literature. Especially, the signal for the proton thiophene at 6.97 ppm, assigned to HT-HT triads^{16,17}

represents more than 99% of the signal. Copolymerization was conducted with different feed rates of **2** (5%, 16% and 25%); at a conversion rate < 10%, the molar fraction of units **2** in the polymer follows the feed ratio (Figure S3, Supporting Information), showing that the comonomers have close reactivities and yield random copolymers.

In the precursor brominated copolymer, the bromide was substituted by p-hydroxyaniline protected as its diphenylmethylenimine (copolymer **B** in Scheme 1). This functionalization yield is higher than 98 % under phase transfer catalyst conditions. The rate of substitution of the bromine was estimated by NMR (Figure S4, Supporting Information) by the comparison of the integrals of the CH₂O protons at 3.87 and the residual integral at 3.43 ppm (shift of the CH₂Br protons). The imine could not be hydrolyzed by acid catalysis in H₂O/THF mixture because it led to phase separations during the reaction. Therefore, the aniline was deprotected by aminolysis with hydroxylamine yielding to the reacting copolymer **PHTcoAHT** (Scheme 1).^{18,19}

First, non-covalent functionalization of SWNTs was performed in order to define a suitable mass ratio SWNT/**PHTcoAHT** allowing one to get a stable suspension of the nanohybrid. For that purpose, we have prepared a mother suspension of SWNTs in THF (175 mg L⁻¹) and added successive amounts of 200 µL (corresponding to 0.32 SWNTs/Copolymer weight ratio) of it to a 4 mL solution of **PHTcoAHT 36000** in THF (28.8 mg L⁻¹). The process was repeated until the suspension became unstable and flocculated. The same procedure was used to prepare suspensions of SWNT/**PHTcoAHT 5000** in THF (concentration of the mother solution of SWNTs in THF: 150 mg L⁻¹, successive additions of 40 µL of it to a solution of **PHTcoAHT 5000** having a concentration of 31.9 mg L⁻¹).

All these suspensions are stable for few hours depending on the concentration of nanotubes, after which they eventually slowly flocculate. However, above a critical SWNTs/copolymer mass ratio, flocculation occurs immediately. This ratio is 1.26 for M_n 36000 g mol⁻¹ and 0.47

for 5000 g mol^{-1} indicating that the longer the polymer chain the larger amount of SWNTs suspended. Such an effect of polymer molecular weight has already been reported for polyfluorene²⁰ and polycarbazole.²¹ It can be emphasized that the stability of SWNT/**PHTcoAHT 36000** suspensions (below the critical mass ratio) for few hours is a first evidence that copolymer chains are in close interaction with nanotubes. Indeed, suspensions of SWNTs in THF (without copolymer) at the same concentration are strongly instable.

Figure 1. Evolution of the (a) optical absorption and (b) photoluminescence spectra of SWNTs/**PHTcoAHT 36000** suspensions as a function of wt. ratio. A weight ratio of 0.32 corresponds to a single addition of SWNTs.

Non-covalent functionalization of SWNTs was monitored by UV-Vis absorption (Figure 1a) and photoluminescence spectroscopy (Figure 1b). Note that the last spectrum displayed on Figure 1 (and Figure S5, Supporting Information) corresponds to the highest weight ratio for which the suspension is stable.

When the concentration of SWNTs increases, UV-Vis spectra show a decrease of the absorption of the free copolymer at 450 nm (2.75 eV) accompanied by a relative increase of a broad unresolved band between 530 nm (2.34 eV) and 630 nm (1.97 eV). Such behavior was previously observed on solutions of regioregular P3HT in various solvents and was assigned

as the signature of the formation of aggregates (crystallites) due to interchain interactions between thiophene units as the chains extend and planarize.^{22,23} On the basis of these results, we can conclude on the formation of such aggregates in the SWNT/**PHTcoAHT** suspensions in THF. The formation of these aggregates is clearly enhanced by the amount of SWNTs present in the suspensions. Consequently, we can reasonably assume that this enhancement is caused by the interaction (π -stacking) of the polymeric chains with the nanotubes. In other words, SWNTs play the role of growth nuclei for the aggregates of **PHTcoAHT** chains. It can be also emphasized that the length of the polymeric chain plays a role in the formation of aggregates; longer the chain is larger the amount of SWNTs suspended (as shown by comparing Figure 1a and Figure S5a). This can be understood as due to the increase of the interaction between polymeric chain and SWNTs with the chain length. Finally, the presence of a weak aggregate band in the solution of **PHTcoAHT** in THF without SWNTs is due to the relatively high concentration of the copolymer in the starting solution. This relatively high concentration was chosen to ensure the dispersion of a sufficient amount of SWNTs to be easily detectable. However, the same experiments performed on low concentrated copolymer solutions show the same behaviour (Figure S6, Supporting Information) and a comparable critical mass ratio is obtained. These results indicate that the concentration of the **PHTcoAHT** solution and the possible presence of initial aggregates have no incidence on the reported overall behaviour.

The photoluminescence (PL) band of **PHTcoAHT** in solution in THF without SWNTs shows a 0-0 emission peak (the most intense) located around 570 nm (2.17 eV) and 0-1 emission peak around 620 nm (2.0 eV) (Figure 1b and Figure S5b, in Supporting Information). The gap between the two emission peaks, close of 0.18 eV, indicates that the C=C symmetric stretch dominates the coupling to the electronic transition.²³

The increase of SWNTs concentration leads to a global decrease of the PL intensity without change of its spectral shape (Figure 1b and Figure S7, Supporting Information) whatever the copolymer concentration (Figure S6, Supporting information). Such a decrease of the PL has already been reported in the literature above a critical concentration of polymer in a solvent or when varying the quality of the solvent (by using a mixture of a good and a bad solvent),^{23,24} and shown to be originated by the formation of weakly emissive aggregates. For our solutions of SWNTs/**PHTcoAHT** in THF, we conclude that the PL quenching without change of the profile when the amount of SWNTs increases can be explained as mainly due to the decrease of the amount of free polymer. This decrease is concomitant with the formation of aggregates growing at the surface of the SWNTs, the growth of such aggregates being controlled by the interaction between the copolymer backbones and SWNTs.^{25,26} This explanation is consistent with the interpretation of the optical absorption spectra measured on the same solutions.

However, opposite to what is reported in the literature,^{23,24} the PL signature of **PHTcoAHT** aggregates is not observed in our SWNTs/**PHTcoAHT** suspensions. Associated with the independence of the PL lineshape on the concentration of aggregated copolymer, this could be interpreted as a weakening or quenching of the aggregates emission originated by their interaction with SWNTs.

Figure 2 compares the UV-vis spectra of a suspension of SWNTs dispersed in water with SDS and of a suspension of non-covalent nanohybrids isolated by precipitation in toluene. This process allows one to eliminate most of the free copolymer and residual bundles of SWNTs from the sample (the solvent extraction method is described in Supporting Information).²⁵ However, it does not modify sensibly the stability of the suspension. The spectrum of the isolated non-covalent nanohybrids clearly shows the superposition of the

absorption spectra of **PHTcoAHT** aggregates, characterized by a band around 500 - 650 nm, and of carbon nanotubes red shifted in the region 1000 – 1500 nm compared to the SDS suspension. The red shift of the optical transitions of the non-covalently functionalized SWNTs is characteristic of strong electronic interactions at the SWNT-copolymer interface.^{26,27}

Figure 2. UV-vis spectra of SWNTs dispersed with SDS (black line, left scale) and non-covalent nanohybrids with **PHTcoAHT** 36000 (red line, right scale) purified by the solvent extraction method.

The results above show the strong π - π interactions between the thiophene units and the aromatic rings of the nanotubes, overcoming the high planarity of such a conjugated regioregular polymer skeleton.²⁸ They are in full agreement with the wrapping of the chains around SWNTs as already reported.²⁹⁻³¹ Moreover, these results suggest that this wrapping

could be made of few stacked chains of copolymers and is more efficient for long polymeric chains.

The covalent hybrids were prepared by carrying out Tour's reaction (Scheme 2) on the non-covalent ones. We chose a SWNTs/copolymer concentration ratio (ratio 0.2 and 0.05 for M_n 36000 g mol⁻¹ and 5000 g mol⁻¹, respectively) well below the critical flocculation ratio determined above to ensure a good dispersion of the tubes. The effect of the temperature of the reaction on the suspension of the non-covalent hybrid has been checked by fluorescence.

Scheme 2. Structure of the copolymers (**PHTcoAHT**) synthesized and of the covalent CNT adduct. $x = 86\%$, $y = 14\%$.

Upon heating up to 60 °C, the fluorescence increases rapidly and after 15 minutes reaches a plateau which probably corresponds to an adsorption-desorption equilibrium between the nanohybrids and the surrounding copolymer solution (Figure S8, Supporting Information). This indicates that the copolymer redissolves at least partially, leading to a possible change in the orientation of the aniline group relative to the nanotubes in the suspension, favoring the

reaction. Important is that Tour's reaction does not affect the copolymer backbone, changes being only observed in the aniline group (see Figure S9 and S10, Supporting Information).

Unlike non-covalent nanohybrids suspensions, the covalent ones are stable up to two months and cannot be isolated by precipitation in toluene. Using the experimental conditions described above for the functionalization of SWNTs, the UV-vis spectrum of both nanohybrids is saturated by the copolymer absorption below 550 nm (Figure 3 for M_n 36000 g mol⁻¹, Figure S11, Supporting Information, for M_n 5000 g mol⁻¹). This prevents the observation of the effect of the functionalization on the SWNTs absorption bands, particularly in the case of a low covalent functionalization rate, as expected.⁷ However, between 1100 and 1500 nm, the SWNTs optical transitions of the non-covalent nanohybrids are red-shifted compared to that of the covalent ones. It indicates that the thiophene units do not stack onto the tubes as easily in the covalent sample as in the non-covalent one. Moreover, the broad band in the range 500 – 600 nm characteristic of thiophene aggregates, present in the UV-vis spectrum of the non-covalent nanohybrids, is absent in that of the covalent one. It shows that covalent functionalization increases the disorder in the copolymer chain packing. These UV-vis results, together with the drastic difference in the stability of the solutions of both nanohybrids, clearly show that the organization of the copolymer in both systems is different.

Figure 3. UV-vis spectra of the covalent (blue line right scale), and non-covalent (red line left scale) SWNT/**PHTcoAHT 36000**.

Examples of Raman spectra excited at 633 nm of thin films prepared from suspensions of raw, non-covalently (weight ratio of 1.26) and covalently functionalized SWNTs are shown on Figure 4. The Raman modes of SWNTs, i.e. the D band around 1320 cm^{-1} and the G modes in the $1500 - 1600\text{ cm}^{-1}$ range, appear close for the three samples with a D/G intensity ratio slightly higher in the covalently functionalized SWNTs. This is consistent with the expected low amount of covalent grafting (10^{-3} per C atom) corresponding to a large distance between defects, of the order of 2 - 3 nm, and thus negligible changes in D/G ratio.^{8,31} On the contrary, the lineshape of the modes of the **PHTcoAHT**, located in the $1350\text{-}1500\text{ cm}^{-1}$ range, and assigned to the C-C intra-ring and C=C in-plane symmetric stretching modes respectively (note that these designations do not take into account the complex nature of these collective

bond stretching modes;^{32,33} however they are sufficiently entrenched in the literature that they have become useful labels irrespective of their accuracy), are different in the non-covalent and covalent samples (Inset Figure 4). It is well established that Raman spectroscopy is deft at probing subtle structural differences at the local order in the polymer stacking,^{32–35} consequently these spectral changes indicate clearly that the organization of the copolymer is not the same in both samples.

Concerning non-covalent nanohybrids, the lineshape of the modes around 1380 cm⁻¹ and 1450 cm⁻¹ is close from the ones obtained on pure polymer thin films as well as those typically reported for “annealed” films in the literature (see Figure 2 of Ref. 35 for example).

On the contrary, the covalent samples appear different and unusual on two different aspects: 1) the appearance of a mode at 1425 cm⁻¹ in the C=C vibrations range and 2) an upshift and broadening (or splitting with the appearance of a high frequency component) of the C-C band around 1380 cm⁻¹. Some similarities can be found with the spectra of regiorandom P3HT (RRa-P3HT).³⁴ In particular the Raman spectra excited at 633 nm in Ref. 34, the mode around 1380 cm⁻¹ displays a double peak structure in RRa-P3HT against a single narrow peak in RR-P3HT. This behavior observed for RRa-P3HT is however accompanied by an upshift and a broadening of the C=C band which is dispersive as a function of laser wavelength which is in disagreement with our observations on the covalent SWNT/**PHTcoAHT** samples. Overall, the position and intensity of the C-C mode can be modulated by disorder but also by chemical substitution in C₃.³³ However, the latter can be rejected as after Tour’s reaction the copolymer backbone is not modified (Figure S9, Supporting Information) and its Raman spectrum unchanged (Figure S10, Supporting Information). Moreover, based on the calculations,³⁵ a splitting of the C=C mode, with calculated frequency of each component close with our experimental data, is only expected in the so-called torsional configuration. This

configuration is plausible as a consequence of the covalent link to the SWNTs, the appended aniline acting as a spacer between SWNTs and the **PHTcoAHT** skeleton.

Figure 4. High frequency range of Raman spectra (excitation wavelength 633nm) of thin films of raw SWNTs (black), **PHTcoAHT 36000** (green), non-covalent (red) and covalent (blue) SWNT/**PHTcoAHT 36000** normalized at 1590 cm^{-1} . Inset: zoom of the thiophene C-C and C=C stretching modes in SWNT/**PHTcoAHT 36000** non-covalent (red) and covalent (blue) nanohybrids; all the spectra are normalized at 1450 cm^{-1} .

CONCLUSION

In summary, we have synthesized a copolymer derived from regioregular P3HT in which about 15% of the monomers bear an aniline group at the end of the hexyl side chain. Like P3HT, this copolymer is able to disperse SWNTs in THF by forming non-covalent

nanohybrids in the form of one or few layers of chains wrapping around the nanotubes. Starting from these non-covalent systems, a covalent reaction with SWNTs is performed. Despite the small amount of material used in the present study preventing XPS and TGA analysis, the stability of the covalent nanohybrids suspensions and the comparison between both covalent and non-covalent nanohybrids characterizations show that the copolymer organizes differently at the interface with the nanotubes in each case. Due to the covalent grafting by **PHTcoAHT** side chains, the copolymer adopts a torsional configuration preventing π interactions between SWNTs and thiophene units. These results are in full agreement with the effectiveness of the reaction.

EXPERIMENTAL

General methods

All the reactions were carried out under argon atmosphere with dry freshly distilled solvents under anhydrous conditions unless otherwise noted. Tetrahydrofuran (THF) was distilled from Na/Benzophenone. All other chemicals were purchased from commercial suppliers (Aldrich and ACROS) and used without further purification. Chromatographic separations were carried out with silica gel (Geduran 40-63 μm).

NMR spectra were recorded on a Bruker WH-400 MHz spectrometer in CDCl_3 and were reported in δ ppm relative to Me_4Si . The FTIR spectra were recorded on a Bruker Vertex 70 spectrometer equipped with ATR diamond reflection unit (MVPStar).

Size exclusion chromatography: The dry samples (5 mg) were dissolved in THF (5 mL) and a few drops toluene as the flow marker were added and the solution filtered (PTFE, 0.45 μm). 100 μL of the solution was injected on a Shimadzu HPLC equipped with a diode array UV detector (SPD-M20A), an Optilab T-rEX refractometer from Wyatt Technology, and a TREOS light scattering detector from Wyatt Technology). The solution was analyzed with a 4

PL gel mixed C column, thermostated at 35 °C, and calibrated with 15 linear PS standards from Polymer Lab. Preparative SEC was performed on a LaboACE LC-5060 from Japanese Analytical Industries, on a JAIGEL-2HR and JAIGEL-2.5HR columns.

UV – Vis – NIR spectra were recorded with a Varian Cary 5000 or a Perkin Elmer - Lambda 25 spectrometer.

Fluorescence spectra were measured with a Horiba-Jobin-Yvon E348 Fluorimeter. A triangular cell was used allowing the analysis of the same solutions as those characterized by UV-vis by getting rid of possible internal filter effects. A rectangular cell (10mm x 10mm) has been used to characterize low concentrated solutions (Figure S6b, Supporting Information).

Raman spectra were recorded using an Acton SP2500 spectrometer fitted with a Pylon CCD detector and a 1800 grooves/mm grating. The samples were excited with a 633 nm (1.96 eV) laser (HeNe, Newport) through 50x objective (Numerical Aperture 0.5) and 0.1 mW impinging on the sample.

Synthesis

The synthesis of the two monomers used is detailed in the supporting information (SI section I-A and I-B)

Poly(3-hexylthiophene-co-3-(6-bromohexyl)thiophene) (A): in a 200 mL reactor equipped with a UV-Vis probe (optical path 151 μ m), a solution of dry LiCl (464 mg, 10.9 mmol) in THF (120 mL) was stirred at 0 °C. *i*-PrMgCl (2M in THF) was added slowly until the absorption of the organomagnesium between 250 and 270 nm was persistent. 2-bromo-3-hexyl-5-iodothiophene **1** (751 mg, 2.0 mmol) and 2-bromo-3-(6-bromohexyl)-5-iodothiophene **2** (159 mg, 336 μ mol) were added. *i*-PrMgCl (2 M in THF) was added slowly until no more than 90 % of the monomer is metallated. Aliquots of the medium were sampled,

quenched with CD₃OD and the amount of metallated monomers measured (singlet at 6.90 ppm, Figure S1, Supporting Information). The mixture was heated to 20 °C and Ni(dppp)Cl₂ (68 mg, 127 μmol, 0.04 equiv) was added. Reaction was followed by absorption at 440 nm. The reaction was quenched with two drops of aqueous HCl (2 M). The solution was partially evaporated and the polymer was precipitated in methanol (10 x the volume of the solution). The polymer was separated from supernatant by centrifugation (9500 rpm, 1 h) and dried under vacuum for 24 h to yield pure **A** (543 mg, 97%). The copolymer was dissolved in CHCl₃ and further purified by preparative GPC.

¹H NMR (400 MHz, CDCl₃): δ (ppm) 6.99 (s, thiophene C4-H), 3.43 (t, *J* = 6.8 Hz, CH₂Br), 2.81 (m, thiophene-CH₂), 1.89 (p, *J* = 6.9 Hz, CH₂CH₂Br), 1.71 (m, hexyl C2-H₂), 1.57-1.25 (m, 6H, hexyl C3-H₂, CH₂CH₃ and hexyl C4-H₂), 0.92 (m, 3H, CH₃);

¹³C NMR (100 MHz, CDCl₃) δ (ppm): 140.1 (thiophene C3), 139.7 (bromohexylthiophene C3), 133.9 (thiophene C5), 130.7 (thiophene C2), 128.8 (thiophene C4), 34.0 (CH₂Br), 32.9 (bromohexyl C5), 31.8 (hexyl C4), 30.7 (hexyl C2), 30.5 (bromohexyl C2), 29.6 (hexyl C3), 29.4 (hexyl and bromohexyl C1), 28.8 (bromohexyl), 28.2 (bromohexyl), 22.8 (hexyl C5), 14.3 (CH₃);

FTIR (ATR diamond) ν (cm⁻¹): 3055 (aromatic νCH), 2953 (ν_{as}CH₃), 2920 (ν_{as}CH₂), 2852 (ν_sCH₂), 1562, 1509 and 1453 (aromatic νCC), 1376 (δCH₃), 1261, 818, 723;

Poly(3-hexylthiophene-co-3-(6-(4-(diphenylimino)phenoxy)hexyl)thiophene) (B): in a pressure tube, K₂CO₃ (29 mg, 210 μmol, 1.22 equiv) was suspended in a solution of Bu₄NBr (35 mg, 108 μmol, 0.63 equiv) and 4-[(diphenylmethylene)amino]phenol (48 mg, 172 μmol, 1.00 equiv) in DMF (2 mL). A solution of copolymer **A** (204 mg, 1.15 mmol, 172 μmol of bromohexyl) in THF (30 mL) was added and the sealed tube was heated to 95 °C for 4 days. THF was removed in vacuum and the crude was precipitated in ten times its volume of

MeOH. The polymer was recovered by centrifugation (9500 rpm) and dried 24 h under vacuum (211 mg, 89% yield).

^1H NMR (400 MHz, CDCl_3): δ (ppm) 7.70 (d, $J = 7.2$ Hz, imine phenyl), 7.47-7.33 (m, 0.44 H, imine phenyl), 7.25 (m, imine phenyl), 7.10 (m, 0.28 H, imine phenyl), 6.99 (s, 1H, thiophene C4-H), 6.65 (m, 0.57 H, $J = 8.4$ Hz, aminophenol H), 3.87 (t, 0.28 H, $J = 6.3$ Hz, CH_2O), 2.80 (m, 2H, thiophene- CH_2), 1.71 (m, 2H, thiophene- CH_2CH_2), 1.49-1.40 (m, 2H, hexyl C), 1.35 (m, 4H, CH_2CH_3 and thiophene- $(\text{CH}_2)_3\text{CH}_2$), 0.92 (m, 3H, CH_3).

^{13}C NMR (100 MHz, CDCl_3) δ (ppm): 175.1 (C=N), 155.6 (Aryl C-O), 151.7, 144.4 (Aryl C-N), 140.3 ($\text{Ph}_2\text{C}=\text{N}$ phenyl C1), 140.1 (thiophene C3), 136.8 (Ph_2CN phenyl C4), 135.9 (phenyl), 133.9 (thiophene C5 HTHT), 130.6 (thiophene C2), 129.7, 129.3, 128.8 (thiophene C4), 128.6, 128.4 (C2 thiophene), 128.3, 128.1, 125.7, 122.7, 114.5, 34.4 (CH_2 -thiophene protected amine), 31.9 (CH_2 -thiophene hexyl), 30.7 (CH_2CH_2 -thiophene hexyl), 30.5 (CH_2 - CH_2 -O), 29.6 ($\text{CH}_2\text{CH}_2\text{CH}_2$ -thiophene hexyl), 29.5, 29.4 ($\text{CH}_2\text{CH}_2\text{CH}_3$), 26.1 ($\text{CH}_2\text{CH}_2\text{CH}_2$ -O), 22.8 (CH_2CH_3), 21.3, 14.3 (CH_3);

FTIR (ATR diamond) ν (cm^{-1}): 3054 (aromatic νCH), 2953 ($\nu_{\text{as}}\text{CH}_3$), 2922 ($\nu_{\text{as}}\text{CH}_2$), 2853 ($\nu_{\text{s}}\text{CH}_2$), 1608 (imine νCN), 1564, 1501 and 1453 (thiophene νCC), 1446, 1376 (δCH_3), 1315 (aryl C-N stretching), 1238 (νCO ether), 1166 ($\nu\text{C-O}$ ether), 1104 and 958, 819 (oop thiophene CH), 783 (imine phenyl CH bend), 724 (methyl rock), 693 (imine phenyl CH bend).

Poly(3-hexylthiophene-co-3-((4-aminophenoxy)hexyl)thiophene) (PHTcoAHT): a solution of copolymer **B** (58 mg, 280 μmol , 40 μmol of imine) and hydroxylamine (0.1 mL, 33 mmol, 35 equiv) in THF (2 mL) was heated to 50 $^\circ\text{C}$ under Ar for 20h. The resulting polymer was precipitated in MeOH, separated by centrifugation (9500 rpm, 1 h) and dried

under vacuum for 24 h. A shiny violet solid was obtained (50 mg, 98 % yield) (SI section I-E).

^1H NMR (400 MHz, CDCl_3) δ (ppm) 6.99 (s, 1H, **CH** thiophene HT-HT coupling), 6.96, 6.73(d, 2H, $J = 8.2$ Hz, phenyl C2-H and C6-H), 6.62 (d, 2H, $J = 8.2$ Hz, **CH** phenyl C3-H and C5-H), 5.02 (s, NH₂), 3.89 (t, 2H, $J = 6.4$ Hz, **CH₂O**), 2.81 (m, 2H, **CH₂**-thiophene HT coupling), 1.71 (m, 2H, **CH₂**-CH₂ -thiophene), 1.44 (m, 2H, **CH₂**-CH₂ -CH₂ thiophene), 1.35 (m, 4H, CH₂**CH₃** and thiophene-(CH₂)₃**CH₂**), 0.93(m, 3H, **CH₃**);

^{13}C NMR (400 MHz, CDCl_3) δ (ppm): 140.1 (**C3** thiophene HTHT). 133.9 (**C5** thiophene HTHT). 130.7 (**C2** thiophene HTHT), 128.8 (**C4** thiophene HTHT). 116.6, 115.8, 31.9 (**CH₃**). 30.7(CH₂CH₂-thiophene hexyl), 30.5, 29.6 (CH₂CH₂CH₂-thiophene hexyl), 29.4 (CH₂CH₂CH₃), 22.8 (CH₂CH₃), 14.3 (CH₃);

FTIR (ATR diamond) ν (cm^{-1}): 3361 (large, NH stretching), 3053 (CH aromatic stretching), 2953, 2922 and 2853 (aliphatic CH stretching), 1608 (NH bend), 1562 (NH bend), 1510 and 1454 (asymmetric and symmetric ring stretching), 1377 (methyl def.), 1236 (C-O alkyl aryl ether), 819 (aromatic CH out of plan), 724 (methyl rock).

Elaboration of the nanohybrids.

HiPCO SWNTs (mean diameter 1.0 +/- 0.2nm) have been purchased from NanoIntegris. They were dried at 250 °C under vacuum prior to use.

Dispersion of SWNTs in SDS solution. 10.5 mg of sodium dodecyl sulfate (SDS) were dissolved in 4 mL of D₂O. 1.98 mg of SWNTs were added to this solution and the mixture was sonicated for 5 min (tip sonication, 20% of 500 W, Fischer Scientific Model FB-505) then centrifuged (25000 g for 80 min). The supernatant was collected and characterized.

SWNTs mother suspension. 0.7 mg of SWNTs were dispersed in THF by sonication (5 minutes). Sonication was repeated for 30 s before every use.

Non-covalent nanohybrids were prepared by adding a given volume of the SWNTs mother solution to a solution of copolymer of known concentration. The mixture was then sonicated for 5 minutes (tip sonication, 20% of 500W, Fischer Scientific Model FB-505) to get the non-covalent hybrids.

Covalent nanohybrids were prepared by Tour's reaction on suspensions of SWNTs/**PHTcoAHT** in THF (weight ratio of 0.2 and 0.05 for **PHTcoAHT 36000** and **5000** respectively to ensure a good dispersion of SWNTs). 10 equiv. of isoamyl nitrite with respect to the amine groups were added to the suspensions and the resulting mixtures were heated at 65 °C for 12 h in a sealed Schlenk's vial. The product of the reaction was centrifuged during 5 minutes at 25000 g and the supernatant was recovered and characterized.

Sonication has no effect on the UV-vis and fluorescence characteristics of a solution of pure copolymer.

Thin films for Raman were prepared by spin coating from a THF solution onto a glass plate then rinsed with THF.

SUPPORTING INFORMATION

The Supporting Information is available free of charge on the ACS Publications website at DOI:

Details on monomer synthesis, copolymer synthesis and characterization, and copolymer modification and characterization; optical absorbance spectra of nanohybrids obtained with **PHTcoAHT 5000**; solvent extraction method; and temperature effect on the non-covalent nanohybrids.

ACKNOWLEDGEMENTS

C. Foussat and the facility of polymer characterization are acknowledged for the SEC measurements and for the use of the UV and FTIR spectrometer. J.M. Catala is acknowledged for helpful discussions. M. P., J.-L. S., P. J. M. and P. P. acknowledge financial support from the ANR GAMBIT project, Grant No. ANR-13-BS10-0014 of the French Agence Nationale de la Recherche.
