Keywords: Supercapacitors; Electrochemical energy storage; Surface modification; Cobalt hydroxide; Ionic Liquids

Abstract: Nano oxides and hydroxides generate great interest as promising positive electrode materials for the development of high energy density supercapacitors. However, their usually limited ionic and electronic conductivities significantly decrease their energy storage performances when increasing the electrode's mass loading. Here, we report on a sonochemical approach to functionalize the surface of $\text{Co}(\text{OH})_2$ nanomaterials by EmimBF_4 ionic liquid that greatly improves the stability and the electrochemical performances of high mass loading electrodes (13 mg/cm^2). This surface functionalization boosts the transport properties and strongly enhances the capacity as well as the capacity retention at higher current densities compared to basic $\text{Co}(\text{OH})_2$ (e.g. 113.5 C/g vs. 59.2 C/g at 1 A/g). Additionally, the protective layer formed by the ionic liquid stabilizes the electrode material upon cycling in KOH aqueous electrolyte and protects the material from oxidation upon open-air storage.

One of the biggest challenge in supercapacitor research area consists in increasing their energy density, which is, in the current supercapacitors, still limited for several applications into renewable energy storage or transport sector. A possible way to face this challenge is to develop high capacitance electrodes based on nanostructured pseudocapacitive or battery-like materials.¹ Indeed, the latter materials have the ability to achieve rapid redox reactions that can deliver a higher energy density than adsorption/desorption mechanisms currently observed for carbon-based electrodes used in the commercial EDLC.² These last years, different oxides/hydroxides such as RuO₂, MnO₂, Co₃O₄, Ni(OH)₂, Co(OH)₂, NiCo₂O₄, have been studied for that purpose.^{2,3} Among these materials, cobalt hydroxide has attracted attention due to its layered structure that allows a good ionic mobility, its high theoretical capacity (2076 C/g considering 2 electrons exchange) and relatively low cost. Additionally, Deng et al. determined recently that the oxidation/reduction processes generate only minor structural changes enabling excellent rate performances and high cycling life.⁴ Cobalt hydroxide can be synthesized in two different phases: the α -form is described as positively charged Co(OH)_{2-x} sheets separated by interlayered anions (NO₃⁻, Cl⁻ ...) to compensate the charge and the brucite-like β -form of Co(OH)₂, which is reported as a hexagonal close-packed structure of hydroxyl ions with Co(II) occupying octahedral interstices one plane out of two.^{5,6} In the α -form, the presence of anionic species together with water molecules generates bigger interlayered spacing compared to those in β -Co(OH)₂, however the α -Co(OH)₂ is metastable and quickly evolve to β -form in alkaline solution.⁷

Various synthesis approaches such as sol-gel, hydrothermal, precipitation or electrodeposition leading to different original morphologies of nanostructured Co(OH)₂ or hybrid carbon-Co(OH)₂ materials are reported in the literature. For instance, Ranganatha et al. reported a sol-gel synthesis of mesoporous α -Co(OH)₂,⁸ Wang et al. synthesized flower-like α -Co(OH)₂ by precipitation method,⁹ Fu et al grown pine needle β -Co(OH)₂ on nickel foam,¹⁰ and Darbandi et al. communicated on the preparation of β -Co(OH)₂ nanorings by chemical precipitation.¹¹ Although these electrode materials reported in the literature present most of the time good electrochemical performances and high specific capacities, the active material mass loading used in these studies is usually very low and not adapted for real devices (see Table 1). In fact, electrode mass loading should be above 10 mg.cm⁻² in hybrid supercapacitors in order to validate the gravimetric capacity of full devices and the absence of study with adequate mass loading does not allow to evaluate the real potentiality of Co(OH)₂ electrode material.^{12,13} It is well known that increasing mass loading leads usually to increase the charge transfer resistance

and to slow down ionic diffusion, that finally lowers the specific capacity.^{14,15} For instance Jagadale et al. reported for α -Co(OH)₂ a drastic drop in capacitance from 386.4 F.g⁻¹ (193 C.g⁻¹) to 150 F.g⁻¹ (75 C.g⁻¹) for a slight increase in electrode active mass loading (from 2.5 to 3.1 mg.cm⁻²).¹⁶ Similarly, Ranganatha et al. have shown that the specific capacitance is consequently lowered when increasing mass loading levels (mass loading of 0.5-0.6 mg.cm⁻², 2.4-2.5 mg.cm⁻² and 4.7-4.8 mg.cm⁻² lead to a capacitance of ~ 450 F.g⁻¹, ~ 270 F.g⁻¹ and ~ 150 F.g⁻¹ respectively).¹⁷

To face this problem and optimize the transport properties, the surface modification of the active material could be an ideal issue. For instance, a surface modification by ionic liquids (IL) “functionalization” can reshape the surface properties or bring new ones (e.g. hydrophobicity), alter the interface reactivity or reduce the surface defects.^{18–20} Concerning the conduction properties, the group of Tarascon found that LiZnSO₄F-IL, synthesized by ionothermal approach, exhibits a RT ionic conductivity four orders of magnitude higher than the basic LiZnSO₄F.²¹ Interestingly, Choi et al. have also demonstrated by DFT calculations that the functionalization of Co(OH)₂ surface by the BmimBF₄ ionic liquid permits faster ion diffusion and easier hydrogen adsorption/desorption processes on Co(OH)₂.²² However, in their work, the synthesized nanohybrid material, Co(OH)₂-IL, has a different size/morphology and a 6 time higher specific surface area than their benchmark Co(OH)₂, which makes impossible to evaluate experimentally the sole influence of the surface modification on the ionic diffusion and energy storage performances.²² Additionally, the mass loading of their electrode was not high enough for practical application. In this work, we develop a sonochemical assisted method to synthesize Co(OH)₂-IL nanohybrids and investigate the influence of the surface functionalization on the energy storage performances of high mass loading electrodes (13 mg.cm⁻²), by comparing Co(OH)₂-IL with the benchmark Co(OH)₂ material of similar size/morphology. EmimBF₄ (1-ethyl-3-methylimidazolium tetrafluoroborate) was chosen for this study due to its higher conductivity compared to BmimBF₄ (1-butyl-3-methylimidazolium tetrafluoroborate) and other imidazolium based ionic liquids with longer alkyl chains.²³

Synthesis: Co(OH)₂-IL was prepared by ionic liquid assisted sonochemical method. In a first step, 3.18 g of Co(NO₃)₂·6H₂O were dissolved in a mixture of 5 mL of H₂O, 5 mL of ethanol and 2 mL of EmimBF₄ (1-ethyl-3-methylimidazolium tetrafluoroborate), then 10 mL of 3M NaOH was added to the cobalt solution. Immediately after the addition, the solution was sonicated during 30 min (with pulses of 7 s “on” and 3 s “off”). The pink powder was then collected by centrifugation, washed several times in ethanol and dried at 60°C overnight. The same procedure was done without IL to obtain the benchmark Co(OH)₂.

XRD analyses: A Philips Panalytical X’Pert Pro diffractometer was used to record X-ray powder diffraction patterns. A Co K_α radiation was used in order to avoid fluorescence problematic with traditional Copper sources and to generate high quality patterns. The powder diffraction patterns were recorded for about 4 h in the 10°–110° (2θ) angular range, with a 0.0167° (2θ) step size and a 2.122° (2θ) active width in the detector.

Scanning electron microscopy (SEM) images were taken on the metallized samples (Pd-deposited) by a Hitachi Model S-4500 microscope.

Fourier transform infrared (FT-IR) spectra were recorded by using a Bruker Equinox 55 spectrometer in the wavenumber range of 400–4000 cm⁻¹ (mid-IR) with a resolution of 4 cm⁻¹. The samples were finely ground in a mortar with dried KBr in an approximate ratio of 1: 40 (by wt.%).

XPS experiment: The X-ray photoelectron spectroscopy analyses (XPS) were performed with the Thermo K-alpha spectrometer with a hemispherical analyzer and a microfocussed monochromatized radiation Al K_α line (1486.6 eV) operating at 75 W under a residual pressure of 1 x 10⁻⁷ mBar. The analysis area was ca. 200 μm² and a pass energy of 20 eV was used for core peak records. The use of neutralizer gun, which sprays the low energy electrons and Ar⁺ ions over the sample surface, to minimize the surface charging was necessary. All the binding energies were referenced to the C 1s peak at 285.0 eV originating from the adventitious carbon (always detected at surface of materials). Core peaks were analysed using a nonlinear Shirley-type background and peak positions and areas were obtained by a weighted least-squares fitting of model curves (70% Gaussian, 30% Lorentzian) to the experimental date. Quantification of surface composition was based on Scofield’s relative sensitivity factors.²⁴

The Auger Electron Spectroscopy (AES) analyses were carried out with a JEOL JAMP 9500F Auger spectrometer (JEOL Ltd, Tokyo, Japan) working under UHV conditions (pressure $< 2.10^{-7}$ Pa). The UHV equipment was a Schottky field emission Auger electron spectrometer (FE-AES) allowing a high lateral resolution (~ 10 nm) analysis and a high brightness.

AES spectra (kinetic energy from 0 to 1000 eV) were carried out at a constant retarding ratio (CRR) mode with $dE/E = 0.5\%$ (high sensibility) at an acceleration voltage of 15 keV and a probe current of 5 nA (working distance = 23 mm and sample tilt angle = 30°).

Scanning Auger Maps (SAM) were recorded at constant retarding ratio (CAE) operating conditions and an acceleration voltage of 15 keV with a probe current of 5 nA (working distance = 23 mm and sample tilt angle = 30°).

Electrochemical measurements were performed in aqueous 5M-KOH electrolytes in a three electrode mode at room temperature. Platinum wire was used as counter electrode whereas Hg/HgO was used as reference electrode in the basic electrolyte. The working electrodes were prepared with a mixture of active material / carbon black / polytetrafluoroethylene in a weight ratio of 80/15/5. A disk of about 7 mm diameter of the electrode material, with a weight of ~ 8 mg, was pressed during 30 s at 5 bars on a nickel foam (current collector). It results in a 8 mm disk and hence an active material loading of ~ 13 mg/cm². The three electrodes (working electrode, reference electrode and counter electrode) were placed in the electrolyte in order to form an equilateral triangle and each electrode was separated from the two others by ≈ 16 mm. Electrochemical impedance measurements were performed under open-circuit condition. A small AC perturbation amplitude of 10 mV versus the open-circuit potential was applied in a frequency range from 50 kHz down to 0.1 Hz. Cyclic Voltammetry (CV), Constant Current Charge/Discharge (CCCD) and Electrochemical Impedance Spectroscopy (EIS) were performed using a EC-lab potentiostat.

Results: Both syntheses (with and without ionic liquid) lead to pure and well crystallized β -Co(OH)₂ as it is confirmed by X-ray diffraction (see Figure 1a) and deduced from the pink color of the polycrystalline powders. The presence of the ionic liquid during the sonochemical synthesis does not influence the nature of the polymorph as in the hydrothermal synthesis reported by Jana et al.²⁵ and has no influence on the morphology as in the synthesis approach reported by Choi et al.²² Indeed, figure 2 shows that both Co(OH)₂ and Co(OH)₂-IL are characterized by polydispersed platelets with a width ranging from about 50 to 300 nm. During

the synthesis, the ionic liquid does not hinder the platelets growing and/or Ostwald ripening that should be induced by the heating of the synthesis media and particle's collision generated by ultrasound radiations.²⁶ In fact, the precipitation of Co(OH)_2 happens directly after introducing the sodium hydroxide in the cobalt solution (see Figure S1) and the IL is rather used as reactant to generate the surface modification. Additional experiments reveal that the α -polymorph can also be formed with this synthesis method by replacing $\text{Co(NO)}_3 \cdot 6\text{H}_2\text{O}$ by CoCl_2 (see Figure S2).

Figure 1b shows the infrared spectra of Co(OH)_2 and $\text{Co(OH)}_2\text{-IL}$. For both materials, the sharp band at $\sim 3629\text{ cm}^{-1}$ (ν_{OH} : stretching of the free hydroxyl groups) and the broad signal peaking at 530 cm^{-1} attributed to Co-O stretching perfectly fit with [to the spectrum](#) of $\beta\text{-Co(OH)}_2$.²⁷ For $\text{Co(OH)}_2\text{-IL}$, the additional signals corresponding to $\nu_{\text{B-F}}$ ($\sim 1084\text{ cm}^{-1}$), $\nu_{\text{C-N}}$ ($\sim 1569\text{ cm}^{-1}$) and $\nu_{\text{C-H}}$ (between 2900 and 3200 cm^{-1}) confirm the presence of EmimBF_4 even after several washing steps,^{18,28} whereas the low intensity peak at 2425 cm^{-1} could be attributed to boron-oxygen bonds. These latter might be formed by the reaction between the decomposition products of BF_4^- and the solvent, indeed BF_4^- can be partially decomposed under ultrasonic radiation and generate F^- ions.^{18,29} The band around 1384 cm^{-1} belongs to N-O stretching vibrations of nitrates that are adsorbed on the particle surface of Co(OH)_2 during the synthesis.⁴

XPS survey has been first recorded, and the orbitals of the elements coming from the Co(OH)_2 materials and from the ionic liquid have been detected (see Figure 3). High-resolution spectra have also been obtained for all the orbitals of the elements detected. The corresponding binding energies (B.E.) and atomic percentages are reported in Table 2.

Co 2p spectrum exhibits two main components due the spin-orbit coupling located, respectively, at 780.5 eV for the Co $2p_{3/2}$ and 797.0 eV for the Co $2p_{1/2}$. Two large peaks, assigned to shake-up satellites, located at 5.7 eV toward the higher binding energies can also be detected. Lower satellites are also observed at 790.6 eV and 806.5 eV . The energy position, the FWHM and the area ratio between the satellites and the main component ($I_{\text{Co2psat}}/I_{\text{Co2pmain}} \sim 0.8$) indicates that the cobalt is in the +2 oxidation state in a hydroxyl environment.³⁰ The O1s spectrum is decomposed in three components: the hydroxyl groups of the bulk materials is assigned to the major component at 531.1 eV . Two other minor

components are attributed to oxide (B.E. O 1s = 529.1 eV) and oxygen from adsorbed species (B.E. O 1s = 532.5 eV).

The N 1s, F 1s and B 1s core peaks are directly associated to the presence of the ionic liquid on the Co(OH)₂ surface. The BF₄⁻ environment is assigned, from the literature,³¹ to the component located at 194.6 eV. The second component at 192.0 eV should be due to the boron atom in an oxygenated environment. This latter supports the partial decomposition of the BF₄⁻ upon sonification as deduced from IR spectrum (see Figure 1b). Two components are also detected in the F 1s core peaks one at 686.5 eV for the fluorine in the BF₄⁻ anions, and the other at 684.3 eV due to chemisorbed fluorine on the material surface.³² The ratio between the fluorine and the boron assigned to the “BF₄⁻” environment reaches 3.2. The imidazolium N 1s signal of the cation is well detected at 401.9 eV in accordance with the literature.³³

The C 1s spectrum (not shown here) exhibits three components attributed to the hydrocarbonated species (285 eV), the C-O and C-N environments (286.5 eV) and the adsorbed species (289.2 eV).

Finally, in addition to the Infrared data, the XPS analyses confirm the grafting of the ionic liquid on the Co(OH)₂ materials surface with a I(N 1s_{401.9}) / I(Co 2p) ratio of 0.08. These results are also supported by Auger analyses revealing on several single Co(OH)₂ particles nitrogen and boron signals corresponding to the ionic liquid fingerprint (see Figure S3).

In order to investigate the effect of the surface modification on the energy storage performances, galvanostatic charge/discharge (GCD), cyclic voltammetry (CV) as well as electrochemical impedance spectroscopy (EIS) measurements were performed on both Co(OH)₂ and Co(OH)₂-IL electrode materials. The influence of the nickel foam on the capacity was investigated and can be considered as negligible (see Figure S4). The CV curves (see Figure 4a) show that the two materials present two highly reversible oxidation peaks that might be assigned, according to the literature, to the oxidation of Co and leading to H_xCoO₂ phases.^{34,35} The functionalization of Co(OH)₂ surface by EmimBF₄ triggers higher intensity oxidation and reduction peaks, leading to a higher capacity. Additionally, it seems to induce a slight shift of the redox peaks that lowers the polarization upon cycling (especially for P2/P'2: 0.12 V and 0.085 V for Co(OH)₂ and Co(OH)₂-IL respectively), suggesting a higher reversibility and better kinetics. The GCD curves (see Figure 4b) confirm the battery-like signature and the increased specific capacity for the hybrid material. This latter, evaluated from the discharge curve, is 113.5 C/g at 1 A/g for Co(OH)₂-IL against 59.2 C/g at 1 A/g for Co(OH)₂. Besides the capacity is nearly doubled for the functionalized material, the capacity retention when increasing the

current density is also improved (see Figure 4c-d). For instance at 5 A/g, the capacity is maintained at 96.8 C/g (85.7% of capacity retention compared to the capacity at 1 A/g) whereas it is only at 39 C/g (67% of capacity retention) for the bare Co(OH)₂.

In order to deeper investigate the effect of the ionic liquid, CV measurements at various scan rate were performed (see Figure S5). The evolution of the intensity versus the scan rate was further analyzed using the power-law relation (equation (1)):

$$i(V) = \alpha v^b \quad (1)$$

Here i is the intensity at a defined potential V , α and b are two constant and v is the scan rate value. Based on the work done by the groups of Dunn and Long,^{36–38} a plot of $\log(i)$ versus $\log(v)$ allows to determine to the b -value which gives useful information about the transport dynamics and the charge storage mechanism. A b -value of 1 corresponds to a surface limited process (e.g. adsorption of ions / capacitive storage) whereas a b -value of 0.5 indicates a charge storage mechanism limited by semi-infinite diffusion (solid-state diffusion of cations through the electrode material / faradaic charge storage). We study the b -value using the cathodic currents with sweep rate ranging from 2 mV/s to 20 mV/s. At a potential of $E = 0.15$ V (see Figure 5a), which corresponds mainly to a faradaic region, the b -value of 0.5 for Co(OH)₂ traduces a purely semi-infinite diffusion mechanism whereas the surface functionalization of Co(OH)₂ by EmimBF₄ leads to a b -value of 0.72. This higher b -value suggests a more surface limited charge storage mechanism and/or limited diffusion mechanism. At $E = 0.33$ V (see Figure 5b), which should rather correspond to (pseudo)capacitive region, the b -value of 1 for Co(OH)₂-IL confirms a surface limited process whereas the lower b -value (0.68) is rather characteristic of a finite diffusion process. Although the high mass loading electrodes (13 mg.cm²) may influence the b -value, in both regions Co(OH)₂-IL presents better kinetics. Indeed, a synergic effect happens between the Co(OH)₂ and the EmimBF₄ which has a high intrinsic conductivity (15 mS.cm⁻²) that optimizes the transport properties of the hybrid material.³⁹ These obtained results fit well to the theoretical calculations, which conclude that the adsorption/desorption of the proton is facilitated by the ionic liquid.²²

For a better comprehension of the interfacial processes, EIS measurements were performed at open-circuit potential. Nyquist plots of Co(OH)₂ and Co(OH)₂-IL, represented figure 5c, are characterized by a semi-circle at high frequencies corresponding to the charge transfer resistance (R_{CT}) at the interfaces and a slope at low frequencies assigned to Warburg impedance (Z_W). The trend of the R_{CT} value, obtained using the equivalent circuit represented in the inset,

suggests that the ionic liquid optimizes the interfacial exchanges ($R_{CT} = 1.35 \, \Omega$ and $1.9 \, \Omega$ for $\text{Co(OH)}_2\text{-IL}$ and Co(OH)_2 respectively) (See Table S1 for data refinement). Although the particle's size and morphology as well as the cationic part of the ionic liquid differ, these values are close to the ones reported by Choi et al. ($1.53 \, \Omega$ and $2.59 \, \Omega$ for the nanohybrids and the bare material respectively). The hybrid material electrode presents also better diffusion properties that are characterized by a more vertical Warburg slope at low frequencies (Figure 5c). Finally, the surface modification induces a better stability of the electrode material upon long-term cycling ~~and thus, a better capacity retention~~. Indeed, for $\text{Co(OH)}_2\text{-IL}$ the charge transfer resistance does not evolve after 5000 cycles at 2 A/g whereas it strongly increases for Co(OH)_2 (Figure 5c and Table S1). Similarly, the impact of long-term cycling on the ionic diffusion is detrimental for Co(OH)_2 whereas it is nearly negligible for $\text{Co(OH)}_2\text{-IL}$. Figure 5d shows the capacity evolution for both electrode materials upon long-term cycling performed at 2 A/g in 5M-KOH. For $\text{Co(OH)}_2\text{-IL}$, the slight increase of capacity (from 105 to 110 C/g) that happens during the first 500 cycles can be attributed to an activation process. Then, the capacity remains nearly constant during 5000 cycles, which, together with the excellent coulombic efficiency, attest the great electrode material stability already observed by EIS. On the other hand, the capacity of Co(OH)_2 progressively decreases upon cycling to reach a capacity retention of 73% after 5000 cycles. Thus, it can be reasonably supposed that the electrode material directly starts to degrade upon cycling. From the EIS and long-term cycling analyses, it can be assumed that the better transport properties for $\text{Co(OH)}_2\text{-IL}$ prevent from mechanical constraints that induce a degradation of the material upon cycling

It is very important to highlight that the surface functionalization of Co(OH)_2 nanomaterials not only improves the stability upon long-term cycling and the energy storage performance, but it also protects the material against moisture and oxidation under air. Figure 1a shows the XRD patterns of both Co(OH)_2 and $\text{Co(OH)}_2\text{-IL}$ after 8-month open air storage. The bare Co(OH)_2 phase becomes black (see Figure S6) and is completely oxidized in a mixture of HCoO_2 and spinel Co_3O_4 whereas $\text{Co(OH)}_2\text{-IL}$ is perfectly stable.⁴⁰ This induces that the IL acts as a protective layer against oxidation and it seems to cover homogeneously the material since no structural evolution could be detected after 8-month air exposure.

To summarize, the XPS, Auger and infrared analyses confirmed that we were able to functionalize the surface of Co(OH)_2 with EMIMBF₄ ionic liquid. The comparison of energy storage performances with the not functionalized material shows that this surface modification produces a synergetic effect between the highly conductive ionic liquid and the Co(OH)_2

extremely beneficial for the electrode material. As demonstrated by the electrochemical measurements, it enhances the transport properties leading to a better ionic diffusion within the high mass loading electrode. This optimization leads to nearly double the specific capacity at 1 A/g and strongly improves the capacity retention at higher current densities. Moreover, the full capacity retention after 5000 cycles and the comparison of EIS data before and after the long-term cycling have shown that the protective ionic liquid layer stabilizes the material upon cycling. Additionally, the XRD measurements exhibit that this latter protects the material against oxidation/decomposition during the open-air storage. Finally, this work supports the fact that surface modifications have great influence on the energy storage properties and represent a promising strategy to optimize and control the electrochemical performances of electrode materials.

Figures and Tables

Figure 1. a) XRD pattern of $\text{Co(OH)}_2\text{-IL}$ (red) and Co(OH)_2 (black), and the materials after 8-month air exposure b) Infrared spectra of $\text{Co(OH)}_2\text{-IL}$ (red) and Co(OH)_2 (black).

Figure 2. SEM images of a) $\text{Co(OH)}_2\text{-IL}$ and b) Co(OH)_2 , the tick corresponds to 300 nm.

Figure 3. XPS spectra $\text{Co } 2p$, $\text{O } 1s$, $\text{F } 1s$, $\text{B } 1s$ and $\text{N } 1s$ acquired with $\text{Co(OH)}_2\text{-IL}$.

Figure 4. a) Cyclic voltammetry curves measured in 5M-KOH at 5 mV/s for Co(OH)_2 and $\text{Co(OH)}_2\text{-IL}$ b) Galvanostatic charge and discharge curves of Co(OH)_2 and $\text{Co(OH)}_2\text{-IL}$ at 1 A/g in 5M-KOH c) Capacity retention versus current density. 5 cycles at each current density were performed and the 4 last cycles are plotted d) Galvanostatic charge and discharge curves of $\text{Co(OH)}_2\text{-IL}$ at different current density.

Figure 5. Evolution of the intensity versus the scan rate for Co(OH)_2 and $\text{Co(OH)}_2\text{-IL}$ a) at the cathodic voltage of 0.15 V and b) at the cathodic voltage of 0.33 V c) Nyquist plots of Co(OH)_2 and $\text{Co(OH)}_2\text{-IL}$ performed before and after 5000 GCD cycles at 2 A/g d) Evolution of the capacity and the coulombic efficiency for Co(OH)_2 and $\text{Co(OH)}_2\text{-IL}$ upon 5000 cycles performed at 2 A/g in 5M-KOH.

Table 1: Comparison of the performances of different Co(OH)₂ extracted from the literature. For a better comparison, all the capacity values are reported here in Coulomb per gram.

Phase	Electrolyte	Capacity	Scan rate	Loading mass	Ref
α -Co(OH) ₂	6M KOH	430 C/g	1 A/g	0.8–1 mg/cm ²	8
β -Co(OH) ₂	6M KOH	426 C/g (1066 F/g)*0.4	2 A/g	2 mg/cm ²	25
α -Co(OH) ₂	6M KOH	245 C/g (613 F/g)*0.4	2 A/g	2 mg/cm ²	25
Co(OH) ₂	1M KOH	225 C/g (562 F/g)*0.4	0.1 mA/g	0.14 mg/cm ²	41
α -Co(OH) ₂	2M KOH	343 C/g (429 F/g)*0.8	1 A/g	5 mg/cm ²	9
β -Co(OH) ₂	1M KOH	250 C/g (416 F/g)*0.6	1 A/g	Not mentioned	42
α -Co(OH) ₂	1M LiOH	193 C/g (386 F/g)*0.5	0.4 A/g	2.5 mg/cm ²	16
β -Co(OH) ₂	6M KOH	108.5 C/g (217 F/g)*0.5	0.1 A/g	Not mentioned	43
β -Co(OH) ₂	6M KOH	38 C/g (94 F/g)*0.4	1 A/g	2 mg/cm ²	44
β -Co(OH) ₂ /graphene	6M KOH	192 C/g (480 F/g)*0.4	1 A/g	2 mg/cm ²	44
β -Co(OH) ₂ /graphene	6M KOH	216.5 C/g (433 F/g)*0.5	0.1 A/g	Not mentioned	43
β -Co(OH) ₂ /graphene	1M KOH	412 C/g (1030 F/g)*0.4	9.09 A/g	0.92 mg/cm ²	45
Co(OH) ₂ /grap hene/chitosan	2M KOH	257 C/g (367 F/g)*0.7	1 A/g	2.6 mg/cm ²	46
β -Co(OH) ₂ /CMC	2M KOH	303 C/g	1 A/g	1 mg/cm ²	47
β -Co(OH) ₂	6M KOH	175.5 C/g (351 F/g)*0.5	1 A/g	1.8 mg/cm ²	48
β -Co(OH) ₂	1M KOH	75 C/g (166.7 F/g)*0.45	1 A/g	1.65 mg/cm ²	49
β -Co(OH) ₂ /CNF	2M KOH	534 C/g (1186 F/g)*0.45	1 A/g	4 mg/cm ²	50
β -Co(OH) ₂ /CNT	2M KOH	228.5 C/g	1 A/g	1.86 mg/cm ²	51
α -Co(OH) ₂	1M KOH	260 C/g (473 F/g)*0.55	2 A/g	0.74 mg/cm ²	52
α -Co(OH) ₂	0.5M KOH	218.4 C/g (273 F/g)*0.8	0.75 A/g	1.33 mg/cm ²	53
β -Co(OH) ₂	1M KOH	534.7 C/g (891.2 F/g)*0.6	1 A/g	5.42 mg/cm ²	54
Co ₂ (OH) ₃ Cl	3M KOH	292.5 C/g (450 F/g)*0.65	2 A/g	~0.5 g/cm ²	17
β-Co(OH)₂-IL	5M KOH	113.5 C/g	1 A/g	13 mg/cm²	This work

Table 2: Binding Energies (eV) and atomic percentages (at. %) of Co(OH)₂-IL.
