Abstract

A multi-proxy record of Holocene and late-Pleistocene aeolian mineral dust is reconstructed using a combination of geochemical (trace elements), mineralogical and grain-size analyses on cores from the Hani peatland in north-eastern (NE) China. The dust record displays a sharp increase in dust deposition during the late Holocene in comparison to the rest of the Holocene. This trend is in line with climatic records from the Chinese dust source regions and their downwind areas, which generally show an increase in aridity and aeolian activity during the late Holocene. The larger part of the Chinese dust source regions experienced a gradual increase in effective moisture and vegetation cover reaching maxima during the middle Holocene (6.0–8.0 kyr cal. BP) co-occurring with the minima in dust deposition in Hani. These changes in the dust source regions are likely to have been modulated by the variations in the East Asian summer monsoon (EASM), which is the principal mechanism controlling climate in the region. The intensified EASM during the middle Holocene is also likely to have resulted in a sediment recharge at the margin of the Chinese drylands providing additional material and enhancing the atmospheric dust load after the late-Holocene aridification of the region. Combined together, these changes promoted a remobilization of dust sources increasing the amount of material available for transport by the East Asian winter monsoon (EAWM) and the Westerlies. Human activities might also have played a role in the increased dust emissions during the late Holocene, but further research is needed to assess the extent of those impacts at a regional level.

Introduction

Mineral dust plays a significant role on the global climate system, affecting the radiative balance as cloud nuclei, on the chemical composition of the atmosphere and on the marine and terrestrial biogeochemical cycles by supplying nutrients (Harri-son et al., 2001; Maher et al., 2010; Shoenfelt et al., 2018). Not only mineral dust affects climate, but its emission, transport and deposition are also a function of climatic and environmental changes (Lambert et al., 2008; Maher et al., 2010). Palaeo-dust records are windows through which these interactions can be observed and understood. Palaeo-dust archives have been used as indicators of changes in air mass circulation (Ferrat et al., 2012b), wind strength/intensity (De Jong et al., 2007; Fábregas Valcarce et al., 2003; Filipsson et al., 2011), climate variability (Delmonte et al., 2010; deMenocal et al., 2000) and aridity (Marx et al., 2009; Petherick et al., 2009).

The deserts of northern China are among the largest dust source regions on Earth and account for up to 70% of the total Asian (Zhang et al., 2003) and ~25% of the total global (Ginoux et al., 2004) dust emissions to the atmosphere, respectively. North-eastern (NE) China lies at the northernmost margin of the East Asian summer monsoon (EASM) and is influenced by the interplay between different circulation patterns, mainly the East Asian monsoon (both the EASM and the East Asian winter monsoon (EAWM)) system and the Westerlies. Mineral dust particles from various sources have the potential to be mobilized and transported by these different wind systems. The Siberian High (SH; controlling the intensity of the EAWM) and the Westerlies are the two main circulation systems controlling Asian dust transport, the former is considered to control dust transport in the lower atmosphere (<3000 m), while the latter controls long-range transport at high altitudes (<5000 m; An et al., 1990; Sun et al., 2001; Zhang et al., 1997). This region is therefore a key, yet overlooked, area for the reconstruction of past dust dynamics and their relationship with climate variability and environmental processes.

Peatlands are important palaeoenvironmental and palaeoclimatic archives which offer a wide range of proxies (geochemical, biological and physical) and chronologies extending as far back as the late Pleistocene. This potentially allows the investigation of the interactions between dust and past environmental and climatic conditions/processes at various time and spatial scales (De Vleeschouwer et al., 2014a; Ferrat et al., 2012a, 2012b; Kylander et al., 2007; Pratte et al., 2017; Shotyk et al., 2001; Vanneste et al., 2016; Weiss et al., 2002b). While atmospheric dust studies have mainly focused on ombrotrophic peatlands (i.e. atmospherically fed only), a growing number of studies have shown that minerotrophic peatlands can be used as records of atmospheric deposition of lithogenic elements (Ferrat et al., 2012a, 2012b; Kylander et al., 2007; Weiss et al., 2002b). Peat deposits are widespread in NE China, but have been largely overlooked in dust research, in spite of the relative proximity of some of the largest global dust sources (Bao et al., 2012; Ferrat et al., 2012a, 2012b; Li et al., 2017).

The aim of this work is to make a palaeoclimatic reconstruction of dust deposition over the last 14.5 kyr at Hani peatland in NE China. Combining physical (ash content, bulk density, grain size and mineralogy) and chemical (trace elements) proxies, the specific objectives of this study are to (1) establish the validity of the Hani peatland as a record of atmospheric mineral dust deposition, (2) quantify the dust accumulation rate (AR) and determine the chronology of the dust events, (3) attempt a preliminary source identification of the mineral particles deposited to this site and (4) reconstruct the palaeoclimatic changes occurring in the region and link them to potential climatic events and controlling factors

Material and methods

Study site and sampling

The Hani peatland (42°13'N, 126°31'E; 900 m a.s.l.; 18 km²) is a percolation mire located in the Jilin Province, NE China (Figure 1). It lies in the Longgang volcanic field (LGVF) and is surrounded by numerous volcanic cones, covered by pyroclastic deposits, and crater lakes. The local lithology is mainly composed of alkali basalts, tholeiitic basalts, trachyte and pyroclastic materials of Quaternary age overlying the Archean migmatic group, part of the North China Craton (Bureau of Geology and Mineral Resource of Jilin Province, 1988). The Hani peatland developed by the terrestrialization of a barrier lake that formed after the damming of the Hani River following a volcanic eruption during the latter part of the late Pleistocene (Qiao, 1993). The regional vegetation is composed of a temperate broad leaf-conifer mixed forest. The open areas of the peatland are dominated by *Carex lasiocarpa* and *C. limosa*, while the hummocks are mainly composed of *Sphagnum fuscum* and *S. magellanicum* along with *Betula fruticosa* and *Potentilla fruticosa* (Bu et al., 2013; Schröder et al., 2007).

The study area is under a monsoonal climate, characterized by long dry/cold winters, dominated by air masses from the Asian interior, and short moist/cool summers, under the influence of south-easterly winds from the Western Pacific. The region receives mean annual precipitations of around 775 mm most of which (>80%) falls between May and September via the EASM (Schettler et al., 2006b). The mean annual temperature is 3.4°C, with monthly averages ranging between −18.1°C and 20.7°C (Schettler et al., 2006b). The EAWM and Westerly winds strongly affect the region during winter and especially spring (Chu et al., 2009) when the breakdown of the SH creates cold fronts (Roe, 2009), that is, conditions favourable for the occurrence of dust storms in spring (Chu et al., 2009; Zhu et al., 2013).

Two cores, Hani-1 (42°13'25.0"N, 126°31'02.0"E; 830-cm long) and Hani-3 (42°13'27.0"N, 126°31'11.0"E; 960-cm long) were retrieved from the deepest part, determined by depth probing, of the peatland in October 2012. A monolith was cut (10 × 10 cm width) to sample the upper 50 cm of the Hani-1 core and a Belarusian peat corer with 5-cm diameter was used to collect deeper sections of both cores. The cores were wrapped in plastic film, transferred into PVC tubes and stored in a freezer (−20°C). In the laboratory, the cores were sliced fresh at 1-cm intervals for the first 50 cm and at 2-cm intervals for the rest of the cores. The edges of each subsample were trimmed away, to avoid any con-tamination from the coring process. The thickness of each slice was then measured again to evaluate the loss from the slicing and correct the mid-point depth of each sample.

Age–depth model

The chronological control of the cores is based on ¹⁴C AMS dates. Whenever possible, only aboveground plant macrofossils (mainly *Sphagnum* stems, *Carex* seeds and Ericaceae leaves) were selected based on a protocol developed by Mauquoy et al. (2004), in order to ensure a better accuracy of dates (Table 1). In some samples, bulk peat material was dated as insufficient material was found. A total of 15 samples (3 for Hani-1 and 12 for Hani-3) were submitted to the *Beta Analytic* facility (Florida, US) for AMS radio- carbon dating. The radiocarbon dates were calibrated using the InterCal13 Northern Hemisphere terrestrial calibration curve (Reimer et al., 2013) integrated in the *BACON* package (Blaauw and Christen, 2011). The model was constrained with the surface sample of the cores corresponding to the age of sampling (2012 CE). A composite age-model was reconstructed by aligning Hani-1 and Hani-3 cores based on the obtained radiocarbon ages and the ash content.

Bulk density, ash content and grain-size analyses

The bulk density of the samples was obtained by subsequently weighting a subsample fresh and after freeze-drying. The ash content, used as a surrogate of the mineral matter content, was measured on the same subsamples by loss-on-ignition, that is, combusting at 550°C for 6 h to remove all the organic matter (Chambers et al., 2011). Prior to analysis, a selection of ash samples (135), resulting from the ash content analyses, were submitted to a 1M HCl treatment to remove carbonates and sulphates formed during the ashing process. While thermal combustion is an effective way of removing organic matter, grain aggregates may form during the process depending on sample lithology and mineral content (Murray, 2002). The grain-size distribution was determined by laser diffraction on the acid-insoluble inorganic fraction of bulk samples using a laser-optical particle size analyser (Malvern Masterizer-2000, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences (NIGLAS, China)), after the addition of 10 mL 0.05 mol L^{−1} sodium hexametaphosphate (NaPO₃) and being subjected to a short ultrasound treatment (5 min) to separate particles. The grain-size distribution of the samples was characterized by 75 size classes. The instrument has a range of 0.02–2000 µm and an accuracy of <3% from repeated measurement errors.

Mineralogical analyses

X-ray diffraction (XRD) analyses were performed at NIGLAS, using a Malvern Panalytical XRD system (X'Pert₃ Powder) to determine the mineralogy of the ash fraction of selected samples (*n* = 30). Combustion of peat samples at temperature greater than 450°C has been shown to be the most effective method for removing organic matter for XRD analyses, with minimal alteration of the mineralogy, except for clays (Sjöström et al., 2019). Prior to analysis, the samples were washed with water to remove the soluble salts (Sjöström et al., 2019). The step scanning size was from 10° to 70° with a step size of 0.02° and counting time of 2 s per steps.

Major and trace elements analyses

A total of 350 samples in Hani-1 and 220 in Hani-3 were processed for elemental geochemistry. Samples were freeze-dried and powdered using an agate mortar and pestle. For Hani-1, about 200 mg of dried peat powder was placed in Teflon® vessels (50 mL), and 3 mL of HNO₃ and 1 mL of HF was added to them. Then the vessels were closed and placed in an Acid Digestion Bomb (ADB; placed inside a steel jacket). Then the ADB were placed in an oven for 48 h at 180°C. After cooling down the ADB, the solutions were evaporated to near dryness on a hotplate. Then, the remaining solution were diluted with 2% HNO₃ and transferred

to centrifuge tubes. For Hani-3 as well as the <63 μm fraction of local soils, approximately 100 mg of powdered samples were acid digested until complete dissolution, using a series of steps (HNO_3 and HF, then H_2O_2) in Savillex[®] beakers on a hot plate following De Vleeschouwer et al. (2014b). Selected major (Na, Mg, Al, K, Ca, Fe and Mn) and trace (Ti, Sr, Rb, Zr, Sc, Ba, Y, Cs, REE and Th) element measurements were completed on an Agilent Technologies 7500ce Q-ICP-MS at *Observatoire Midi-Pyrénées* in Toulouse, France as well as *NIGLAS*, in Nanjing in 2018 (also using an Agilent Technologies 7500ce Q-ICP-MS) for core Hani-3 and in Guiyang, in 2013 (ELAN DRC-e Q-ICP-MS) for core Hani-1. The analytical performance was assessed using reference materials: GBW-07603 (bush leaves and twigs), GBW-07358 (stream sediments), NIST SRM1515 (apple leaves) and NIST SRM1547 (peach leaves). Replicate analyses were generally within 10% of each other. The blanks for all elements considered here are <0.01%.

Statistical analyses

A principal component analysis (PCA) was performed on the element ARs using SPSS 21.0.0 software to help identify the sources and processes affecting the distribution of the chemical elements in both peat profiles. A PCA reduces the dimension of a data set and explain as much variability as possible with fewer components (Jolliffe, 2002; Reimann et al., 2008). The PCA was executed in correlation mode on previously log transformed ($\log_{10}$) and standardized (z-scores) data to avoid scaling effects, using a varimax rotation which is a fixed orthogonal rotation that maximizes the loadings of the variables on the components (Eriksson et al., 1999). The z-scores were calculated as $(X_i - X_{\text{avg}})/X_{\text{std}}$, where X_i is the variable (i.e. concentration of the element), while X_{avg} and X_{std} are the series average. A hierarchical clustering analysis (HCA) was applied to the grain size data set using the classes as variables in SPSS 21.0.0. The HCA was used to group together samples with similar grain-size distributions.

Figure 2. Lithostratigraphy of the Hani-1 and Hani-3 cores. Depth records of ash content, bulk density and concentrations of selected elements in Hani-1 (black curves) and Hani-3 (red curves).

Results

Core stratigraphy, bulk density and ash content

The stratigraphy, ash content, bulk densities and elemental concentrations of the peat cores are shown in Figure 2. The plant matter is generally well preserved; however, some variations between darker more humified peat and paler less humified peat is observed. The plant composition is generally dominated by sedges with *Sphagnum* spp. present in various proportions. In Hani-1, from 0 to 21 cm, fresh undecomposed peat is found. From 21 to 100 cm, the peat is yellowish and poorly humified. A more humified and brown peat is found between 100 and 589 cm interspersed with a mineral layer around 180 cm and a thick less humified pale brown peat containing well preserved plants at 290–330 cm. There is a prominent mineral-rich layer (containing coarse sands and clay) from 589 to 639 cm. In the deeper section between 639 and 830 cm, the peat is darker and very humified. In Hani-3, the peat is moderately humified, light brown and contains well preserved plants remain between 50 and 180 cm, where a mineral-rich layer is found at 180–185 cm. From 185 to 600 cm, the peat composition is rather uniform being brown and more humified. Between 600 and 931 cm, the peat is mainly dark brown, characterized by a greater degree of humification and contains distinct mineral-rich layers at 645–649, 683–691 and 723–729 cm. Below 930 cm, the core is composed of silt-rich grey lake sediments.

The bulk density of the peat in Hani-1 and Hani-3 cores ranges between 0.02 and 0.66 g cm⁻³ and 0.05 and 0.28 g cm⁻³ in Hani-1 and Hani-3, respectively (Figure 2). Hani-1 displays mineral-rich layers with values of 0.23–0.34 g cm⁻³ between 502 and 489 cm, 0.48–0.58 g cm⁻³ from 571–578 cm and 0.26–0.66 g cm⁻³ at 601–622 cm of depth. Comparatively, mineral-rich layers in Hani-3 (centred around 647, 685, 727, 759 and 180.5 cm) do not display greater bulk densities.

The ash content varies between 2% and 85% in Hani-1, while it ranges between 5% and 58% in Hani-3 (Figure 2). Hani-1 displays a sharp increase in ash content reaching up to 85% between 583 and 639 cm, within the mineral-rich layer. Peaks in ash content values (32–50%) are observed between 600 and 800 cm of depth as well as at 180.5 cm (58%) in Hani-3. The ash content is lower and more stable between 200 and 600 cm in both cores, averaging $19 \pm 4\%$ and $21 \pm 4\%$ in Hani-1 and Hani-3, respectively. Both cores also display an increase in ash content from 100 cm towards the surface reaching up to 40%.

Age–depth model

The Hani-1 and Hani-3 cores display very similar ages and age–depth models (Table 1 and Figure 3) between 60 and 490 cm. Samples from the bottom of Hani-1 (deeper than 500 cm) core were not available (lost during transfer between Guiyang and Nanjing) for radiocarbon dating, so only the section of 500–930 cm from Hani-3 was used in the reconstruction of that part of the age–depth model and of the dust record. The composite age model (Figure 3) shows that AR is relatively constant from peat initiation at 930–490 cm of depth averaging 0.07 cm yr⁻¹, decreasing to 0.03 cm yr⁻¹ between 490 and 410 cm (Figure 3). From 410 to 180 cm, the AR is 0.06 cm yr⁻¹ and then increases around 0.08 cm yr⁻¹ from 180 cm towards the top.

Grain size and mineralogy

The mean particle size in the Hani record ranges between 11.6 and 257 μm with an average of 18.6 μm , while the median grain size range is 10–18.7 μm (average: $10.5 \pm 1.9 \mu\text{m}$). The samples are dominated by silt-size particles (4–63 μm), but clay (<2 μm) and sand (>63 μm) particles are present in various proportions in every samples (Figure 4). However, the fact that the samples were submitted to loss-on-ignition prior to analysis might have resulted in a compaction of the clays, which means the clay fraction might be underrepresented. The cluster analysis identified three different clusters with distinct enough grain-size distributions (Figure 4). As all samples display a main mode in the silt fraction, the separation of the three clusters is mainly based on the presence of different modes (unimodal, bimodal and polymodal) in the grain-size distribution. Cluster 1 ($n = 74$; composed of three subgroups) represents samples with relatively unimodal grain-size distributions. Cluster 2 ($n = 35$; two subgroups) corresponds to samples presenting a fine subpopulation (<1 μm) in their distribution. The distinction of the two subgroups is mainly based on the amplitude of the main mode. Cluster 3 ($n = 26$; five subgroups) includes samples displaying a coarse subpopulation (>100 μm). The separation of the subgroups in cluster 3 is mainly based on the sand and clay content.

The semi-quantitative estimates of the mineral composition of the ash samples are shown in Table 2. The XRD analyses on the selected core samples show that quartz is the dominant mineral in most samples along with phyllosilicates, plagioclase and K-feldspars (Figure 4). A few samples display greater amounts of plagioclase feldspars, especially at 180.5, 182.7 (1700–1760 cal. BP) and 635.0 cm of depth, where they exceed quartz.

Elemental concentrations and PCA analysis

The lithogenic elements display similar concentration patterns between themselves (Figure 2). Although different digestion methods were used, apart from the mineral layers in Hani-1, the two cores show very similar elemental concentrations. Concentrations of lithogenic elements in both cores are slightly higher below 600 cm of depth and are generally at their lowest level between 600 and 400 cm. Both cores also display a peak in the concentration of most elements, apart from Cs and Rb, around 180 cm. The results of the PCA analyses are shown in Figure 5. In both cores, two principal components (PC) were extracted, explaining 92.4% and 96.0% of the total variance of Hani-1 (12 chemical elements) and Hani-3 (30 chemical elements), respectively. The first PCs account for 68.0% and 60.8% of variance in Hani-1 (Na, Li, Al, Rb, Ba, Ti, Mg, Zr, K) and Hani-3 (REE (except Eu), Cs, Rb, Y, Sc, Al, Th, K and Mg), respectively. PC2 explains 24.4% of the total variance in Hani-1 (Ca, Sr, Fe) and 35.2% in Hani-3 (Ca, Sr, Ti, Zr, Na, Eu, Ba and Fe). The fractionation of the communality, that is, the variance of each element AR explained by the extracted components, is shown in Figure 5. The discrepancies between the PCA results of Hani-1 and Hani-3 are because of a combination of factors. The fact that Ca-AR, Sr-AR and Fe-AR load on a separate PC in Hani-1 is explained by the inclusion of the first 50 cm of the core in the analysis. The Ca, Sr and Fe display a sharp increase in concentrations between 10 and 30 cm (Figure 2). Furthermore, the large mineral layer in Hani-1 is likely driving a large part of the variance of the other elements. If these two sections of Hani-1 core are removed, Ti, Na and Zr load on the same PC as Ca and Sr suggesting similar controlling factor as in Hani-3. Another factor to consider is the fact that the majority of the elements loading on PC1 in Hani-3 core were not analysed in Hani-1, namely, REEs and Cs. This likely means that REEs along with some other lithogenic elements (Y, Cs, Rb, Sc and Al) are controlled by different underlying processes than the other elements.

Figure 3. Age–depth models for Hani peatland constructed using the *BACON* software (Blaauw and Christen, 2011). The grey areas encompass all possible age–depth models while the dotted grey lines indicate the 95% confidence intervals. The orange and dark blue line corresponds to the weighted mean age of each modelled sample for Hani-1 and Hani-3, respectively. Orange (Hani-1) and blue (Hani-3) symbols represent the calendar age distribution of the ^{14}C AMS dates.

Figure 4. Grain-size distributions of the mineral fraction in Hani samples obtained from the clustering analysis ((a) Cluster 1, (b) Cluster 2 and (c) Cluster 3). Each grain-size distribution pattern corresponds to a representative sample selected from the subgroups composing each cluster. Comparison with the distribution of present-day dust samples from (1) passive dust collectors in the Changbai Mountains (average; Li et al., 2017), (2) dust sample from a dust event collected on snow in 2002 in the Longgang region (Chu et al., 2009) and (3) sediment sample selected from a sediment core in lake Sihailongwan (Chu et al., 2009).

Dust flux

As mentioned in section 'Age–depth model', given the similarity of the radiocarbon ages, ash contents and the lithogenic element concentrations in Hani-1 and Hani-3 cores, a composite dust record was reconstructed. The dust AR, that is, dust flux ($\text{g m}^{-2} \text{yr}^{-1}$), was calculated using the sum of REE (excluding Eu, as it displays high loading factors on PC2) applying the following formula (Shotyk et al., 2002): $([\Sigma\text{REE}]_{\text{sample}}/[\Sigma\text{REE}]_{\text{UCC}}) \times \sigma \times \text{PAR} \times 10000$, where $[\Sigma\text{REE}]_{\text{sample}}$ is the sum of REE concentrations in a sample, $[\Sigma\text{REE}]_{\text{UCC}}$ is the sum of REE concentrations in the upper continental crust (143.0 mg kg^{-1} ; Wedepohl, 1995), σ is the sample's bulk density (g cm^{-3}) and PAR is the peat accumulation rate (cm yr^{-1}). REEs were selected on the basis that they behave conservatively and show the highest loading on PC1 (Figure 5). Different elements and references will yield very similar trends and timing, but different estimates of dust ARs (Kylander et al., 2016; Shotyk et al., 2002). For this reason, the dust flux was also reconstructed using Ti as its high loading on PC2 in Hani-3 and PC1 in Hani-1 (Figure 5) suggests that local sources contribute significantly to its record at times (Figure 6b and c). The top 500-cm dust flux reconstruction (last 8 kyr cal. BP) is based on an average of Ti concentrations in Hani-1 and Hani-3, while the bottom 500 cm (8–14.5 kyr cal. BP) is based on Hani-3 core only.

The section composed of lake sediment is not reconstructed in terms of dust deposition as it was probably dominated by runoff that is likely to have overprinted the atmospheric dust signal. If we exclude the lake sediments, Hani peatland represents a 14.5-kyr record of mineral dust deposition. Between 14.5 and 12.0 kyr cal. BP, the dust flux, based on ΣREE , oscillates around $25 \text{ g m}^{-2} \text{ yr}^{-1}$ and displays a peak centred around 11.8 kyr cal. BP (Figure 6b). From 11.7 until 8.0 kyr cal. BP, dust deposition shows a gradually decreasing pattern from 35 to $10 \text{ g m}^{-2} \text{ yr}^{-1}$ interspersed with a few small peaks. The lowest dust deposition rates are observed between 8.0 and 6.0 kyr cal. BP averaging $6.3 \pm 1.3 \text{ g m}^{-2} \text{ yr}^{-1}$. The dust flux increases sharply around 5.7 kyr cal. BP reaching a peak of $35 \text{ g m}^{-2} \text{ yr}^{-1}$ at around 5.1 kyr cal. BP. Between 4.5 and 2.2 kyr cal. BP, dust deposition remains relatively stable averaging $20.7 \pm 4.7 \text{ g m}^{-2} \text{ yr}^{-1}$. The dust flux increases again after 2.0 kyr cal. BP displaying high variability with values between 368 (1.8 kyr cal. BP) and $15 \text{ g m}^{-2} \text{ yr}^{-1}$. The dust flux, based on Ti, displays very similar timing and generally closely matches the dust flux values from ΣREE . A few peaks, showing higher values than for the ΣREE -based flux, are present before 12.0 kyr cal. BP, with values over $50 \text{ g m}^{-2} \text{ yr}^{-1}$, and especially around 1.7 kyr cal. BP, reaching $420 \text{ g m}^{-2} \text{ yr}^{-1}$.

Figure 5. Fractionation of the communality of the accumulation rate of each element after extraction by principal component analysis for (a) Hani-1 (top PCA including top 50 cm and mineral layer; bottom: PCA excluding top 50 cm and mineral layer) and (b) Hani-3 (the communality corresponds to the total variance of an element explained by the extracted components).

Discussion

Trophic status of the peat and major processes controlling the geochemical signal

The trophic status of a peatland might affect how inorganic constituents are archived in a geochemical record. The ash content in Hani averages 24–26% in both cores, in agreement with values found in other Chinese peatlands (>10–25%; Bao et al., 2010; Ferrat et al., 2012a, 2012b; Wei et al., 2012) but higher than values typically found in ombrotrophic peats (generally <5%; Sapkota et al., 2007; Shotyk et al., 1998; Tolonen, 1984; Weiss et al., 2002a). Such high ash contents combined with the fact the Hani peatland is *Carex*-dominated, generally indicative of mineral-rich conditions, are usually typical of a minerotrophic nature. However, given the relative close proximity of some of the largest global dust sources, peatlands of the region receive greater dust deposition which, therefore, results in greater ash contents (Ferrat et al., 2012b; Pratte et al., 2018). Pore-water electrical conductivity in the section of the peatland where the cores were collected is low (45–93 μS), suggesting very limited dissolved materials, while the pH (4.2–5.1) and C/N ratios (18–29) are indicative of mesotrophic to oligotrophic conditions (Schröder et al., 2007). Calcium and strontium concentrations have been extensively used as trophic indicators in peat (Shotyk, 1997; Steinmann and Shotyk, 1997). Ca and Sr concentrations display a slight increase with depth, which could indicate vertical migration following mineral dissolution. However, values increase less than twofold from $0.27 \pm 0.08\%$ and $45.9 \pm 15.3 \mu\text{g g}^{-1}$ for Ca and Sr, respectively, between 25 and 650 cm to $0.57 \pm 0.23\%$ and $87.9 \pm 27.9 \mu\text{g g}^{-1}$ below 650 cm, which is far lower than the 3- to 16-fold increase observed in some minerotrophic peatlands (Pratte et al., 2017; Steinmann and Shotyk, 1997). Taken together, this evidence suggests that mineral dissolution and element remobilization is limited in Hani peatland and hence it can be used as a geochemical dust archive. The PCAs were performed in order to identify chemical elements displaying similar

behaviour and hence being controlled by the same processes. The fact that when including the top 50 cm of Hani-1 core, Ca-AR, Sr-AR and Fe-AR load on a different component (Figure 5; PC2) suggests that they are partially affected by diagenetic processes, such as changes in redox conditions and vertical migration (Steinmann and Shotyk, 1997). However, for the second PCA analysis on Hani-1 and the one on Hani-3, other elements load on the same PC, namely, Na, Ti, Zr and Mg ARs in Hani-1 and Ti, Na, Zr, Eu and Ba ARs on Hani-3. This is indicative that other processes are affecting the geochemical record of these elements, including Ca and Sr. Local rocks and deposits are of volcanic origin and rich in plagioclase feldspars (enriched in Na (albite) and Ca (anorthite) and Eu) and contain pyroxenes (such as Ti-rich augite) and olivine (rich in Mg). Zircons, heavy minerals, are the main host of Zr in soils and its derived products (i.e. atmospheric dust), are found in coarser particles, and therefore generally settle closer to the source area (Martínez Cortizas et al., 2002; Schuetz, 1989; Taboada et al., 2006). Thus, changes in PC2 of Hani-3 (and PC1 of the second PCA on Hani-1) are considered to be indicative of inputs from locally derived particles (Figure 6c). REE along with other lithogenic elements (Y, Al, Sc, Th, Rb) load on a different PC, namely, PC1, and this means that they are controlled by a different process. The immobility of REE in peat deposits is now well established (Aubert et al., 2006; Krachler et al., 2003; Kylander et al., 2007, 2013; Pratte et al., 2017; Vanneste et al., 2016). Numerous studies suggest that for the most part, REEs are found in the finer fractions (Gaiero et al., 2004; Gallet et al., 1996, 1998; Weber et al., 1998). The same feature was observed for Th in atmospheric dust, which is enriched in the clay-sized particles (Castillo et al., 2008; McGee et al., 2016; Muhs et al., 2007). This PC is interpreted to represent longer-range atmospheric mineral dust inputs.

Figure 6. Figure 7. (a) La-Th-Sc and (b) Zr-Th-Sc ternary diagrams based on data from the Hani-3 core. Potential source areas: deserts (squares): Taklamakan (Jiang and Yang, 2019), Qaidam (Zhang et al., 2018), Badain Jaran (Zhang et al., 2018), Gurbantunggut (Zhang et al., 2018) and Ordos (i.e. Mu Us and Hobq; Rao et al., 2011; Zhang et al., 2018); dune fields (triangles): Onqin Daga (Xie et al., 2019; Zhang et al., 2018), Hulun Buir, Horqin and Songnen (Xie et al., 2017); Chinese Loess Plateau (Ferrat et al., 2011); Harbin Loess (Xie et al., 2017) and dust storm (Xie and Chi, 2016). The green area represents the fine fraction of Chinese Deserts, dune fields and loess (Hao et al., 2010; Zhang et al., 2018). Local soils and scoria samples are from this study. Composition of the PAAS and UCC are from Taylor and McLennan (1985); LGVF basalts from Chen et al. (2007).

Preliminary source assessment

Incompatible elements such as La, Th, Sc and Zr can be useful tracers for source identification. These can be used to differentiate between sources of felsic (high in La and Th) and mafic (high in Sc) compositions (Olivarez et al., 1991; Taylor and McLennan, 1985). A ternary diagram (Figure 7a) of La, Th and Sc composition of Hani samples reflect a mixing between local mafic sources and allochthonous felsic sources. Based on their close similarity to Hani samples, Chinese deserts and dune fields are considered as a general allochthonous source. However, the specific source cannot be distinguished, which is to be expected given that they are derived from well mixed upper continental crustal materials. This is further evidenced by the mineralogical composition displaying significant amounts of quartz and K-feldspars pointing to a felsic source (Table 2). These minerals tend to be enriched in the coarser fraction ($>2 \mu\text{m}$) of dust and loess deposits (Ferrat et al., 2011; Gallet et al., 1996). Although, quartz are generally found in the sand fraction, various processes such as particle impact and salt weathering can produce silt/clay-sized quartz particles (Crouvi et al., 2010; Goudie et al., 1979; Smith et al., 2002). The grain-size distributions in the Hani peat record (average median grain size: $10.5 \pm 1.9 \mu\text{m}$) are similar to those of modern dust-fall samples collected near Hani peatland (mean grain size: $12\text{--}17 \mu\text{m}$; Figure 4–1; Li et al., 2017), dust events in the Longgang area in 2002 (median grain size: $6.8 \mu\text{m}$; Figure 4–2; Chu et al., 2009) and Harbin City in 2011 (mean grain-size: $12.1 \mu\text{m}$; Xie and Chi, 2016) as well as sediments from lake Sihailongwan (Figure 4–3; Chu et al., 2009). While the use of grain size alone to decipher the source of mineral particles is limited by several factors (methodological, similar distribution produced by different processes), it provides further indications for a mainly allochthonous origin of the mineral particles when combined with geochemistry and mineralogy. Additional evidence that the mineral particles deposited in Hani are from far-travelled desert dust is provided by the relative abundance of Zr-Sc-Th (Figure 7b). The composition of Hani samples is close to the compositional field of the fine fraction ($<5 \mu\text{m}$) of deserts, dune fields and loess of China. Concentrations of Zr vary with particle size, that is, finer fractions of dust have lower contents than do coarser ones (Schuetz, 1989).

The La-Th-Sc ternary diagram also shows that some samples display a more mafic composition closer to local soils, scoria and basalts (Figure 7a). This suggests that local source(s) also contribute to the mineral input to Hani peatland. This is further supported by the occurrence of positive peaks in Eu anomaly and the record of PC2 (Figure 6c and e). Alkali and plagioclase feldspars typically have higher Eu contents but lower REE concentrations (Taylor and McLennan, 1985). The peak in Eu anomaly around 1700 yr cal. BP is the most positive (1.68) and displays the highest content in plagioclase feldspars of the record (Table 2). Although top-soils of the region have encompassed important quantities of material from distal dust deposition (Zhao et al., 1997), they inherited the REE signature of the local basaltic rocks and typically show positive Eu anomalies (normalized to Post-Archean Australian Shales (PAAS): $\text{Eu}/\text{Eu}^*_{\text{PAAS}} = 1.29\text{--}1.56$; this study and Schettler et al., 2006a). Scoria fall and tephra deposits, displaying positive Eu anomalies, are also present in the vicinity of the Hani peatland and likely contributed to the mineral supply (Liu et al., 2009). Samples older than 9.5 kyr displaying a positive Eu anomaly generally also show a HREE enrichment ($(\text{La}/\text{Yb})_{\text{PAAS}}$; Figure 6f) and are often characterized by grain-size distributions displaying a mode in the $>100 \mu\text{m}$ fraction (Cluster 3; Figure 4c). Particles larger than $100 \mu\text{m}$ are rarely transported by suspension especially over distances such as those necessary ($>600 \text{ m}$) to reach the core locations and given the heterogeneity and irregularity of the peatland vegetation. Such particles are generally transported by saltation and runoff (Tsoar and Pye, 1987). This is evidenced by the finer main mode and less frequent coarse particles of our core when compared with another core collected at the margin of the Hani peatland (Li et al., 2017). All these evidence points towards more frequent influxes of locally derived minerals during the late Pleistocene and early Holocene.

A binary mixing equation, using an average Eu anomaly from local volcanic sources ($\text{Eu}/\text{Eu}^* = 1.93$) and from the $<75\ \mu\text{m}$ fraction of deserts and dune fields ($\text{Eu}/\text{Eu}^* = 0.89$), was used to obtain a first estimate of local source contribution to the Hani dust record (Figure 6 g). Local sources account for less than 10% of the mineral input in most of the record, apart for a peak around 1.7 kyr cal. BP (66%) and between 9.7 and 10.7 kyr (11–36%) and 12.8–13.5 kyr cal. BP (10–52%). A more extensive investigation of the sources using other REE ratios and more particularly stable isotopes (Nd, Sr, Pb) would be needed to discriminate more precisely between local and allochthonous sources, but more importantly those allochthonous between themselves, that is, the different deserts and dune fields.

Palaeoclimatic implications

Comparison with other climatic records in northern and NE China. As the mineral particles deposited in Hani peatland are mainly of allochthonous origin and derived from the deserts and dune fields of northern China (Figure 7), the Hani record is compared with climatic records from these regions. Dust mobilization and transport is in general directly proportional to wind velocity and the ratio of precipitation/potential evapotranspiration or aridity (impacting on soil moisture and vegetation cover) in the source region (Lancaster, 1988; Tsoar and Pye, 1987), hence our record is compared with records of aeolian intensity and moisture/aridity.

Comparison with records of aeolian activity.

The Hani profile is compared with various aeolian records from northern and NE China, including lake records from arid/semi-arid China and downwind of dust source areas, late Pleistocene and Holocene loess and dune sand/palaeosol records in dust source regions. Most of these records are consistent with ours, displaying greater aeolian activity during the late Pleistocene and late Holocene than during the early and especially the middle Holocene. Dust deposition during the late Pleistocene is relatively high compared with the early and middle Holocene (Figure 8m), a feature also found in the maar lake Sihailongwan, a geochemical record of the input of allochthonous siliciclastic material, located 12 km to the north-east of Hani (Figure 8k; Schettler et al., 2006a). A clear peak in dust ARs (12.2–11.8 kyr cal. BP), displaying an allochthonous felsic composition, is observed during the Younger Dryas (YD; Figure 8m). This increase in dust deposition is also present in the Sihailongwan maar record. While late-Pleistocene records of aeolian activity other than loess are limited, intensified aeolian activity, based on grain-size fractions, was recorded in lake sediments of arid Central Asia and Lake Qinghai during the YD (An et al., 2011, 2012). Enhanced aeolian activity was also inferred from dune records along the southern margin of the Chi-nese desert of northern China during late Pleistocene and the YD (Lu et al., 2013; Stauch, 2019).

Terrestrial records (lakes and peatlands) of aeolian activity from potential dust source regions and downwind areas display a similar pattern as Hani dust deposition during the Holocene (Figure 8i–k). The aeolian records of lake Xiarinur (Figure 8i; proportion of 15–63 and $>150\ \mu\text{m}$ fractions; Xu et al., 2018), in the Onqin Daga dune fields, and lake Tuolekule (mean and $>63\ \mu\text{m}$ fraction; An et al., 2011), in NW China, based on the particle grain size, both show that aeolian activity was relatively low in the early Holocene, reached a minimum in the middle Holocene, and increased after 6.0 kyr cal. BP. Downwind of the dust source regions, a peat bog record of mineral dust deposition, based on REE and Pb isotopic composition, also supports an increase in aeolian activity during the late Holocene on the eastern Qinghai-Tibetan Plateau (Ferrat et al., 2012a, 2012b). In NE China, lake Sihailongwan shows a gradually decreasing trend in aeolian dust deposition from the early to the middle Holocene (Figure 8k; Schettler et al., 2006a, 2006b; Zhu et al., 2013), while a minima in aeolian activity is suggested during the middle Holocene when compared with the late Holocene by the aeolian dust fraction ($<37\ \mu\text{m}$; Figure 8l) in Gushantun peat record (Li et al., 2017) and an aeolian quartz flux reconstruction on Cheju Island, in South Korea (Lim et al., 2015).

Records of aeolian sands, implying sand mobility (i.e. increased aeolian activity or dune expansion/build-up), and palaeosols, indicating lower aeolian activity and increased vegetation cover, from dune fields have been extensively studied in the Chinese drylands (Li et al., 2002; Lu et al., 2013; Mason et al., 2009; Sun et al., 2006). A compilation of OSL ages of aeolian sands/palaeosols in over 150 profiles covering the entire Asian dust source regions (see deserts and dune fields in Figure 1a) consistently suggests increased aeolian activity (more ages from aeolian sands) during the late Holocene (last 5 kyr) compared with the early and middle Holocene (more ages from palaeosols; 5–12 kyr; Xu et al., 2018 and references therein). This feature is also apparent across loess/ palaeosols records from the Chinese Loess Plateau, where the highest numbers of OSL ages from aeolian sands were related to the period after 3.4 kyr (Figure 8j), indicating increased aeolian activity in Chinese dust source regions (Porter, 2001; Wang et al., 2014). This is also consistent with a southward migration of the boundary of the deserts and dune fields of China from the middle to the late Holocene (Lu et al., 2013).

Comparison with records of humidity/aridity.

The Hani dust record generally displays higher dust deposition during drier periods reconstructed in terrestrial records from northern and NE China (Figure 8d–h). Several climatic records (temperature and humidity/precipitations) reconstruct drier or colder conditions during the YD in northern and NE China (Fan et al., 2018; Goldsmith et al., 2017; Stebich et al., 2009; Wang et al., 1994; Wu et al., 2016; Zheng et al., 2017). A reconstruction of effective moisture across the Chinese drylands, combining aeolian sand sequences and vegetation reconstructions, suggests a more arid climate during the late Pleistocene followed by gradually more humid conditions throughout the early Holocene (Li et al., 2014). Various records across the Chinese dust source regions suggest the climate was relatively humid during the early Holocene with a trend towards even more humid conditions into the middle Holocene which became significantly drier during the late Holocene (Chen et al., 2015; Goldsmith et al., 2017; Shen et al., 2005; Wen et al., 2010; Xiao et al., 2004; Xu et al., 2018; Zhao et al., 2009). These records include (1) a moisture index synthesized from fossil-pollen records (30) across arid and semi-arid China (Figure 8d; Zhao et al., 2009); (2) a lake-level reconstruction from the closed lake Dali in Inner Mongolia (Figure 8e; Goldsmith et al., 2017); (3) a pollen-based reconstruction of annual precipitations from lake Hulun, NE China (Figure 8f; Wen et al., 2010). However, some records from NE China suggest that conditions were drier during the early Holocene than the late Holocene (Chen et al., 2008, 2019; Stebich et al., 2015; Zheng et al., 2018) more in agreement with observations in arid Central Asia (Chen et al., 2016; Wang and Feng, 2013). Nevertheless, the same pattern of increasing humidity towards the middle Holocene and drying during the late Holocene is present in many of these records (Figure 8h). All these evidence consistently support that the climate gradually got more humid from the early to the middle Holocene and subsequently became drier over the late Holocene across the Chinese dust source regions.

Figure 8. (a) Diatom-based EAWM index from Wang et al. (2012); (b) pollen-based EASM index from monsoonal eastern China (Wang et al., 2010); (c) strength of the Westerlies represented by the winter insolation gradient between 35°N and 55°N (Chen et al., 2016); (d) moisture index synthesized from pollen-based records in eastern Inner Mongolia (orange line) and arid/semi-arid China (black line; Zhao et al., 2009); (e) lake level of Lake Dali, Inner Mongolia (Goldsmith et al., 2017); (f) pollen-based annual precipitation (P_a) reconstruction from lake Hulun, Inner Mongolia (Wen et al., 2010); (g) percentage of tree pollens from lakes Dahai, Inner Mongolia (black line; Xiao et al., 2004) and Qinghai, Tibetan Plateau (dashed green line; Shen et al., 2005); (h) pollen-based annual precipitation reconstruction from lake Sihailongwan (Stebich et al., 2015); (i) aeolian activity index from lake Xiarinur (Xu et al., 2018); (j) probability density of aeolian sand dates on the Chinese Loess Plateau (Wang et al., 2014); (k) siliclastic influx ($F\text{-Al}_2\text{O}_3$) to lake Sihailongwan, NE China (Schettler et al., 2006a); (l) grain-size component ($<37\text{ }\mu\text{m}$) in Gushantun (green curve) peatland (Li et al., 2017); and (m) Hani peatland non-local dust flux from allochthonous sources (this study). LH: late Holocene; MH: middle Holocene; EH: early Holocene; YD: Younger Dryas.

Over the last 6.0 kyr cal. BP, three peaks in dust deposition centred around 5.0, 1.5 and 0.5 kyr cal. BP are found in the Hani record (Figure 8m). While, the earlier peak is not as ubiquitous as those discussed above, a number of records, mostly in the eastern part of the Chinese dust areas, suggest a shift in climate. The OSL dating of sand/palaeosol profiles from deserts of northern China (Mu Us, Hobq, Horqin and Hulun Buir) displays a transition from palaeosol to aeolian sands between 5.7 and 4.4 kyr BP, suggesting a rapid drying (Li et al., 2007). In addition, lake-level and lacustrine pollen records display a decline in precipitation at 5.3–4.5 kyr cal. BP in Inner Mongolia (Figure 8d–f; Goldsmith et al., 2017; Wen et al., 2010). The two following peaks broadly fit in the general late Holocene decrease in effective moisture that is consistently reported across arid and semi-arid China (Shen et al., 2005; Wen et al., 2010; Xiao et al., 2004; Xu et al., 2018).

To summarize, a large proportion of the records located in the Chinese dust areas, their downwind regions and NE China are consistent with the Hani peatland dust deposition record indicating drier conditions and high aeolian activity during the late Holocene, which suggests a relationship between aeolian activity, aridity/effective moisture and dust deposition in the region. However, discrepancies with some records in NE China and arid Central Asia suggest some spatial heterogeneity.

Potential controlling factors.

Asian dust emission and transport is mainly controlled by the Westerlies and the EAWM through the forcing of the SH (Sun et al., 2001). Modern dust storms in northern China mainly occur in spring (March, April, May) during the breakdown of the SH creating cold fronts (Roe, 2009). However, the similarity between the different potential source areas (Figure 7a) currently prevents the identification of a precise source and, by extension, which system controls dust supply to Hani peatland. Furthermore, comparing our dust deposition record with the dust-based index of the EAWM from Huguang Maar lake (Figure 8a; Wang et al., 2012), the late Holocene (middle Holocene) high (low) dust flux occurs during a period of low (high) EAWM intensity, which suggests that the Hani record is not the direct result of the variations in EAWM.

The similarity of the Hani record with records of aeolian activity and aridity/humidity from arid and semi-arid China (Figure 8), along with the allochthonous felsic geochemical composition of the mineral particles (Figure 7), implies that the dust supply to Hani peatland is controlled by the climatic and environmental changes occurring in the dust source regions of China. Changes in aridity have widely been invoked to explain increased dust emissions (Biscaye et al., 1997; Harrison et al., 2001; Rea and Leinen, 1988). Nevertheless, as discussed by Marx et al. (2018), major dust sources, such as the deserts and dune fields across northern China, are located in already arid environments, in which moisture levels rarely inhibit dust emission. Other factors, such as vegetation cover, sediment recharge and wind intensity can play an important role on dust availability. However, some of these factors are partially controlled by moisture/precipitation levels such as vegetation cover and sediment recharge.

Modern observations on dune mobility in northern dune fields suggest that changes in wind strength (aeolian intensity) alone has limited effect on the mobilization/stabilization of dunes and other factors need to be involved (Mason et al., 2008). In arid and semi-arid regions, vegetation is very sensitive to effective moisture (the balance between precipitations and potential evapotranspiration; Liu et al., 2005). The relationship is evidenced by a similar trend of the vegetation cover reconstruction with those of humidity/aridity. Deserts and dune field areas were reduced during the middle Holocene (Dallmeyer et al., 2015; Lu et al., 2013), the eastern dune fields (Mu Us, Onqin Daga, Hulun Buir and Horqin) being nearly entirely covered by vegetation (Lu et al., 2013; Yang et al., 2013).

The palaeoclimatic and palaeoenvironmental changes observed in the dust source regions of China are consistent with the Holocene variability of the EASM and suggest that precipitations in arid and semi-arid China was controlled by this mechanism (Wang et al., 2010). Most of the deserts and dune fields are located in the marginal zone of the EASM where it plays a significant role in the hydrological balance and effective moisture, especially in the eastern dune field regions (Lu et al., 2005; Winkler and Wang, 1993). The EASM records from northern China monsoon frontal area, including a EASM index from a meta-analysis of moisture/temperature records (92) across monsoonal China (Figure 8b; Wang et al., 2010), tree pollen from Dahai and Qinghai lakes (Figure 8g; Shen et al., 2005; Xiao et al., 2004), reconstructed precipitations from Lake Gonghai (Chen et al., 2015), lake levels from lake Dali (Figure 8e; Goldsmith et al., 2017) consistently suggest that the strength of the EASM gradually increased during early Holocene, reaching its maximum intensity and northward extent during the middle Holocene (6–7 kyr cal. BP) and subsequently gradually decreased from 4–6 kyr cal. BP with a southward retreat (Dong et al., 2018; Wang et al., 2010, 2014).

The entire desert belt experienced wetter conditions between 8 and 4 kyr depending on the regions (Yang et al., 2011). It is reasonable to think that an enhanced intensity and a further northern limit of the EASM during the middle Holocene could have resulted in a sediment recharge along the margin of the Chinese drylands affected by the EASM. The subsequent weakening of the EASM and corresponding increased aridity during the late Holocene would result in greater sediment availability and potentially greater atmospheric dust loads.

The case of the YD is of particular interest. While a dust peak is observed in the Hani record, it is not as prominent as those observed during the late Holocene and its time span is short lived (11.8–12.2 kyr cal. BP; Figure 8m). The EASM records consistently display a weakening during the YD (An et al., 2012; Chen et al., 2015; Dykoski et al., 2005). Assuming that the relationship between the Hani dust record and the climatic/environmental changes in the Chinese dust source regions still holds for the YD, this would suggest that the region was also drier during the YD. However, there are discrepancies among the humidity/precipitation records during the YD (Goldsmith et al., 2017; Li et al., 2017; Schettler et al., 2006b; Stebich et al., 2015; Zhou et al., 2010), so it is still unclear what controlled humidity during this period. Some of the discrepancies might be ascribed to the fact that some of these records are based on single proxies which encompass climatic signal differently from one to another. The lower dust flux might partially be explained by the presence of permafrost in some regions and longer frost seasons, inhibiting dust entrainment (Jin et al., 2000; Parplies et al., 2008).

To summarize, dust deposition in Hani displays a close resemblance to the aridity/humidity and aeolian intensity records from the Chinese dust source regions and their downwind areas. An inverse relationship is observed where minima (maxima) in dust deposition correspond to maxima (minima) in effective moisture/precipitations and vegetation cover in the various proxy records. The similarity of this pattern with the known Holocene variability of the EASM suggests that climatic changes in the Chinese drylands are controlled by this mechanism. Hence, the climatic conditions created by the weakening of the EASM during the late Holocene created conditions favourable for the mobilization of dust by the EAWM or the Westerlies (Figure 8), which was deposited in Hani peatland downwind.

Superimposed on these climatic mechanisms is the potential influence of human activities, especially during the late Holocene. There is increasing evidence of human occupation and activities in Chinese drylands as early as around 7.0 kyr cal. BP, but more significantly after 2.0 kyr cal. BP (Dodson et al., 2009; Schültz and Lehmkuhl, 2009; Zhuo et al., 2013). Further research is needed

to assess the significance of anthropogenic activities on dust emissions in northern China's drylands since it is clear that this is a factor that impacted the environment during the late Holocene (Schultz and Lehmkuhl, 2009; Zhu et al., 1989; Zhuo et al., 2013).

Conclusion

Elemental concentrations, combined with mineralogy and particle grain size, in a 9.3 m long peat section from the Hani peatland, from the Changbai Mountains (NE China), allowed for the reconstruction of variations in dust deposition over the late Pleistocene and the Holocene. The dust record displays a sharp increase in dust deposition during the late Holocene in comparison to the rest of the Holocene, in line with climatic records from the Chinese dust source regions and their downwind areas, which generally record increased aridity and aeolian activity during the same period. These changes in the dust source regions are likely to have been modulated by the variations in the EASM, which is the principal mechanism controlling climate in the region. Combined together, these changes promoted a remobilization of dust sources increasing the amount of material available for transport by the EAWM and the Westerlies. Human activities might also have played a role in the increased dust emissions during the late Holocene, but further research is needed to assess the extent of those impacts at a regional level.

Acknowledgements

We are grateful to Rongqin Liu for lab assistance at NIGLAS. The ICP-MS service of OMP (A Lanzanova, C Duquenoy) as well M-J Tavella (EcoLab) are acknowledged for assistance with sample preparation and Q-ICP-MS measurements. We are thankful to two anonymous reviewers for their constructive comments on a previous version of the manuscript.

Funding

The author(s) disclosed receipt of the following financial support for the research, authorship and/or publication of this article: This research was supported by the NSFC-CNRS Joint Research Project (grant no. 41611130163) to KB and FDV, the Chinese Academy of Sciences President's International Fellowship Initiative (PIFI; grant no. 2017PC0078) to SP, and the National Nature Science Foundation of China (NSFC; grant no. 41971113) to KB.
