Abstract

The external structure of the spray-flamelet can be described using the Schvab-Zel'dovich-Liñan formulation. The gaseous mixture-fraction variable as function of the physical space, $Z(x_i)$, typically employed for the description of gaseous diffusion flames leads to non-monotonicity behaviour for spray flames due to the extra fuel supplied by vaporisation of droplets distributed into the flow. As a result, the overall properties of spray flames depend not only on Z and the scalar dissipation rate, χ , but also on the spray source term, S_v . We propose a new general coordinate variable which takes into account the spatial information about the entire mixture fraction due to the gaseous phase and droplet vaporisation. This coordinate variable, $Z_C(x_i)$ is based on the cumulative value of the gaseous mixture fraction $Z(x_i)$, and is shown to be monotonic. For pure gaseous flow, the new cumulative function, Z_C , yields the well-established flamelet structure in Z -space. In the present manuscript, the spray-flamelet structure and the new equations for temperature and mass fractions in terms of Z_C are derived and then applied to the canonical counterflow configuration with potential flow. Numerical results are obtained for ethanol and methanol sprays, and the effect of Lewis and Stokes numbers on the spray-flamelet structure are analyzed. The proposed formulation agrees well when mapping the structure back to physical space thereby confirming our integration methodology.

Keywords: counterflow diffusion flame, spray-flamelet, cumulative mixture fraction, monotonic variable, Schvab-Zel'dovich-Liñan formulation

1. Introduction

Spray combustion is present in a variety of industrial technologies, such as diesel engines, gas turbines and liquid-propellant rockets [1]. As a result, modelling it is an important subject that has attracted considerable attention in the scientific community for many decades. [2, 3, 4, 5, 6]. Unlike gaseous diffusion flames, that are governed by the competition between scalar mixing and chemistry, spray flames are also influenced by evaporation and mass transport of the liquid-fuel into the reaction zone [7], making it a more complex problem.

Due to the importance of spray flames, several numerical and theoretical investigations have been performed to understand the main physical and chemical processes that govern spray combustion as well as their flame structure in different spatial and temporal scales [2, 7]. Regarding numerical investigations, two different approaches can be highlighted: (i) Eulerian Interface Capturing (EIC), and (ii) Particle Tracking (PT) methods. For EIC, Changxiao *et al* [8] developed a computational framework that resolves the interface of the dispersed phase for the atomization, evaporation and combustion processes. In order to capture the interface, the authors combined level set and ghost fluid methods. Their methodology requires that the computational mesh is of the order of the droplet size, which very quickly results in large meshes that demand the use of extensive computational resources. In spite of the fact that their methodology permits to obtain very accurate results, their approach can be intractable if a supercomputer is not used. Particularly, for three-dimensional problems such as that presented in [8]. For PT, Large-Eddy Simulations including a two-phase flow model were performed by Irannejad *et al* [9]; the gaseous phase field was solved using a Eulerian framework and the liquid spray phase using a two-way Lagrangian stochastic method. The authors considered methanol spray combustion and obtained good agreement with experimental data. However, similar to [8], the simulations performed in [9] also required extensive computational resources.

Theoretical investigations of the spray-flame structure can give important physical insights into the behaviour of spray flames in simple configurations. Such insights can then be used as a basis to understand more complex combustion systems [7]. Traditionally, the flame structure of laminar gaseous diffusion flames is studied in terms of the gaseous mixture fraction Z [10], a passive scalar that is an appropriate variable to analyse the mixing of the reactants (the dominant physical process in these type of flames).

Besides enabling a more computationally efficient solution in composition space compared to the physical-space solution, the mixture fraction concept is widely used in turbulent combustion models, since it allows the turbulent flame to be described in terms of simple one-dimensional elements called flamelets [11]. Extending this formulation to spray-flames would in principle enable the analysis tools developed for gaseous flames to be applied. However, a direct extrapolation of the classical mixture fraction to spray-flames is not possible

because Z becomes non-monotonic due to the presence of vaporisation sources
45 [7, 12, 13, 14]; the constraint of monotonicity is required to guarantee that the
solution is single-valued. In addition to Z , other composition spaces have been
proposed and analysed in previous studies such as the total mixture fraction [15,
16, 17], and the conserved mixture fraction [7]. The aforementioned alternatives
do not have their monotonicity guaranteed mainly due to differential diffusion
50 and the relative velocity that exists between the liquid and gaseous phases. An
effective composition variable combining the gaseous mixture fraction and the
liquid-to-gas mass ratio was applied to the analysis of counterflow spray-flames
in [7]. This variable was then employed to derive the governing equations for a
spray-flamelet formulation. Although this formulation was found to reproduce
55 the response of the flame structure to variations in the droplet diameter and
strain rate, it required the use of a closure model for the scalar dissipation rate,
 χ [18].

The main objectives of this work are: (i) to propose an alternative monotonic
variable that enables the description of spray-flames and apply it to a simple
60 canonical problem (e.g. counter flow configuration) to highlight the method-
ology. This new variable, termed cumulative mixture fraction, Z_C , consists of
integrating the usual gaseous mixture fraction Z over physical space, x , but
weighted by a normal distribution. It results in an initially increasing func-
tion that reaches a plateau, therefore remaining single-valued and guaranteeing
65 monotonicity; (ii) to formulate the spray-flamelet equations in Z_C -space. An
interesting outcome of this formulations is that no extra model is necessary for
the scalar dissipation rate, χ , as its dependence is directly obtained from the
 Z_C equations; and (iii) to present simulation results, in both x - and Z_C -space,
for ethanol and methanol droplets. Special attention is given to the effect of the
70 Lewis and Stokes numbers on the spray-flamelet structure.

This manuscript is organised as follows: in Section 2, we present the Schvab-
Zeldovich-Liñán formulation for the spray-flamelet model for both the gaseous
phase and the liquid droplets. In Section 3, we derive the model's equations in
terms of the strictly monotonic cumulative mixture fraction, Z_C . In Section 4,
75 we present results for the counterflow configuration with potential flow. Finally,
concluding remarks are presented in Section 5.

2. Physical model

The governing equations are formulated in an Eulerian framework, assuming
steady-state and the low-Mach number limit for the gas phase [19, 20]. For sim-
80 plicity, infinitely fast chemistry is considered (Burke-Schumann limit), enabling
the diffusion flame to be described in terms of the extended Shvab-Zel'dovich
model [21]. In analogy to the theory for gaseous flames, the model developed
here can be extended by relaxing these considerations.

A single global reaction step is used to represent the combustion processes
according to

where $\bar{Q}$ is the heat release and the stoichiometric mass coefficient is defined as
85 $\nu = m_O/m_F$.

2.1. Governing equations in physical space - x

2.1.1. Gaseous Phase

The gaseous phase is described in $\mathbf{x} = \{x_1, x_2, x_3\}$ -space by the following
dimensionless conservation equations of mass, momentum, fuel/oxidant mass
90 fractions, and energy [19],

$$\frac{\partial}{\partial x_i}(\rho u_i) = \alpha_0 S_v, \quad (1a)$$

$$\frac{\partial}{\partial x_i}(\rho u_i u_j) = \frac{\partial}{\partial x_i} \left(\frac{Pr}{Pe} \mu \frac{\partial u_j}{\partial x_i} \right) - \frac{\partial p}{\partial x_j} + \alpha_0 S_v u_{lj} - g_j, \quad (1b)$$

$$\frac{\partial}{\partial x_i}(\rho u_i Le_O Y_O) = \frac{\partial}{\partial x_i} \left(\frac{\Gamma^\gamma}{Pe} \frac{\partial Y_O}{\partial x_i} \right) + \dot{\omega}, \quad (1c)$$

$$\frac{\partial}{\partial x_i}(\rho u_i Le_F Y_F) = \frac{\partial}{\partial x_i} \left(\frac{\Gamma^\gamma}{Pe} \frac{\partial Y_F}{\partial x_i} \right) + \dot{\omega} + S_v, \quad (1d)$$

$$\frac{\partial}{\partial x_i}(\rho u_i \Theta) = \frac{\partial}{\partial x_i} \left(\frac{\Gamma^\gamma}{Pe} \frac{\partial \Theta}{\partial x_i} \right) - Q\dot{\omega} + S_v(\alpha_0 T_l - q), \quad (1e)$$

where $\mathbf{u}_l$ is the liquid velocity and $\mathbf{g}$ the drag force; the remaining symbols are listed in the nomenclature. The heat transfer from gas to liquid is accounted by the last two terms in the right-hand side of Eq. (1e). The non-dimensional mass fractions and temperature are defined as

$$Y_O \equiv \frac{\bar{Y}_O}{Y_{O\infty}}, \quad Y_F \equiv \frac{Le_O \nu \bar{Y}_F}{Le_F Y_{O\infty}}, \quad \Theta \equiv \frac{Le_O \bar{T}}{Y_{O\infty} T_\infty}. \quad (2)$$

The subscripts $-\infty$ and ∞ represent the fuel and oxidant ambient conditions, respectively. Thus, $\bar{Y}_{O\infty}$ and $\bar{Y}_{F-\infty}$ are the oxidant and fuel mass fractions in the incoming streams. The dimensionless variables and characteristic quantities are given by:

$$\rho = \frac{\bar{\rho}}{\bar{\rho}_\infty}, \quad x_i = \frac{\bar{x}_i}{\bar{l}_c}, \quad u_i = \frac{\bar{u}_i}{\bar{u}_c}, \quad p = \frac{\bar{p}}{\bar{\rho}_\infty \bar{u}_c^2}, \quad g_j = \frac{\bar{l}_c}{\bar{\rho}_\infty \bar{u}_c^2} \bar{g}_j, \quad \alpha_O = \frac{\bar{Y}_{O\infty}}{Le_O \nu}, \quad (3a)$$

$$\dot{\omega} = \frac{l_c}{\rho_\infty u_c \alpha_O} \bar{\dot{\omega}}, \quad Q = \frac{\bar{Q}}{\nu c_p \bar{T}_\infty}, \quad q = \frac{\bar{q}}{\nu c_p \bar{T}_\infty}, \quad S_v = \frac{l_c}{\rho_\infty \bar{u}_c \alpha_O} \bar{S}_v. \quad (3b)$$

95

The Peclet and Prandtl numbers are $Pe = \bar{l}_c \bar{u}_c \bar{\rho}_\infty c_p / \bar{K}_\infty$ and $Pr = c_p \bar{\mu}_\infty / \bar{K}_\infty$, respectively, whereas the Lewis number is $Le_j = \bar{K}_\infty / (\bar{\rho}_\infty c_p \bar{D}_j)$ for $j = F, O$ (fuel and oxidant, respectively). The source of mass, S_v , is zero on the oxidant side because the droplets are injected only along the incoming fuel stream. The
100 heat and mass diffusion transport properties are considered to be temperature-dependent, such that $\bar{K}/\bar{K}_\infty = \bar{\rho}\bar{D}/\bar{\rho}_\infty\bar{D}_\infty = \Gamma^\gamma$, with $\Gamma = \Theta/\Theta_\infty$ and $\gamma \neq 0$.

Defining the mixture fraction and the excess of enthalpy as

$$Z \equiv \frac{1 + Y_F - Y_O}{1 + \phi}, \quad H = \frac{\Theta + (Q - 1)Y_F + Y_O}{1 + \phi}, \quad (4)$$

and equating species and energy, Eqs. (1c)-(1e), yields the Schvab-Zel'dovich-Liñan formulation [22, 23, 24, 20],

$$\frac{\partial}{\partial x_i} \left(\rho u_i \int_0^Z L(Z) dZ \right) = \frac{\partial}{\partial x_i} \left(\frac{\Gamma^\gamma}{Pe} \frac{\partial Z}{\partial x_i} \right) + \frac{S_v}{1 + \phi}, \quad (5a)$$

$$\frac{\partial}{\partial x_i} (\rho u_i H_N) = \frac{\partial}{\partial x_i} \left(\frac{\Gamma^\gamma}{Pe} \frac{\partial H}{\partial x_i} \right) + \frac{S_h}{1 + \phi}, \quad H_N = H + \int_0^Z N(Z) dZ \quad (5b)$$

where $S_h = (Q + \alpha_0 T_l - q - 1) S_v$ is the modified heat source, and $\phi = \nu Le_O \bar{Y}_{F-\infty} / Le_F \bar{Y}_{O-\infty}$ is the mixture strength.

The functions $L(Z)$ and $N(Z)$ are given by

$$L = \begin{cases} Le_O, & \text{for } Z < Z_f, \\ Le_F, & \text{for } Z > Z_f, \end{cases} \quad (6a)$$

$$N = \begin{cases} 1 - Le_O, & \text{for } Z < Z_f, \\ (1 - Le_F)(1 - Q), & \text{for } Z > Z_f, \end{cases} \quad (6b)$$

in which quantities at the flame location are denoted by the subscript f . Since the flame is assumed to be infinitely thin, we have that at the stoichiometric plane, $Y_O = Y_F = 0$, leading to $Z_f = (1 + \phi)^{-1}$ and $H_f = \Theta_f(1 + \phi)^{-1}$.

2.1.2. Liquid Phase

The set of droplets present in the spray are assumed to be monodisperse, mono-temperature and monokinetic. While the spray is considered dilute, and interactions between droplets and secondary break-up have been neglected, droplet-gas relative motion due to the droplets inertia is accounted for.

The conservation equations for the liquid phase include the total mass of the droplets, momentum and energy, which are respectively given by

$$\frac{\partial}{\partial x_i} (f_l \rho_l u_{li}) = -\alpha_O S_v, \quad (7a)$$

$$\frac{\partial}{\partial x_i} (f_l \rho_l u_{li} u_{lj}) = -\alpha_O S_v u_{lj} + g_i, \quad (7b)$$

$$\frac{\partial}{\partial x_i} (f_l \rho_l u_{li} T_l) = -\alpha_O S_v [T_l - \tilde{c} \nu (q + L_v)], \quad (7c)$$

where $\tilde{c} = c_p / c_l$ and $f_l = n_l V_l$ is the liquid volume fraction.

The dimensionless variables and characteristic quantities are

$$V_l = \frac{\bar{V}_l}{\bar{a}_0^3} = \frac{4\pi}{3} \left(\frac{\bar{a}}{\bar{a}_0} \right)^3 = \frac{4\pi}{3} a^3, \quad \rho_l = \frac{\bar{\rho}_l}{\bar{\rho}_\infty}, \quad n_l = \bar{a}_0^3 \bar{n}_l, \quad (8a)$$

$$T_l = \frac{\bar{T}_l}{\bar{T}_\infty}, \quad t_c = \frac{\bar{a}_0^2}{\bar{\alpha}_\infty} = \frac{\bar{l}_c}{\bar{u}_c}, \quad L_v = \frac{\bar{L}_v}{\nu c_p \bar{T}_\infty}, \quad \mathbf{u}_l = \frac{\bar{\mathbf{u}}_l}{(\bar{l}_c / \bar{t}_c)}. \quad (8b)$$

Equations (7a) and (7b) can be combined to obtain

$$f_l \rho_l u_{li} \frac{\partial}{\partial x_i} u_{lj} = g_j. \quad (9)$$

The drag force, which accounts for the momentum exchange between gas and liquid phases, is given by $g_j = f_l \rho_l (u_j - u_{lj}) / (a^2 St)$ [25], where $St = t_s^0 / t_c$ is the Stokes number; $t_s^0 = \bar{\rho}_l \bar{a}_0^2 / (72 \bar{\mu}_\infty)$ is the Stokes time for droplets with initial radius $\bar{a}_0$, or alternatively, the characteristic time for the liquid phase to adjust to changes in the surrounding flow field [26]. Equation (9) can then be rewritten to yield

$$u_{li} \frac{\partial u_{lj}}{\partial x_i} = \frac{u_j - u_{lj}}{a^2 St}. \quad (10)$$

In the limit of small Stokes number, i.e., $St \ll 1$, it can be shown that the liquid phase velocity can be asymptotically described as a function of the gas velocity [27]. In this case, an algebraic relation for $\mathbf{u}_l$ can be derived which avoids the computation of the momentum equation, Eq. (7b), for the liquid phase

$$u_{lj} = u_j - a^2 St \left(u_{li} \frac{\partial u_j}{\partial x_i} \right), \quad (11)$$

120 where terms of $\mathcal{O}(St)$ and higher are neglected. Note that the effective Stokes number, $a^2 St$, depends on the square of the droplet radius, a^2 . However, since from the governing equations normalization $a < 1$, the effective Stokes number $a^2 St$ is always guaranteed to be small.

The model for the droplets motion assumes Stokes flow. Put differently, the particle-based Reynolds number, Re_l , must be smaller than 1, i.e., $Re_l = 2 \bar{\rho}_l \bar{u}_c \bar{a}_0 / \bar{\mu}_\infty = Re(2 \bar{a}_0 / \bar{l}_c) < 1$. It can be shown that the aforementioned condition is met for Stokes numbers

$$St < \frac{\bar{\rho}_l / \bar{\rho}}{18 Re}. \quad (12)$$

125 Using representative gas-phase Reynolds numbers, $Re \sim 500$, and mass densities ratios, $\bar{\rho}_l / \bar{\rho} \sim 1000$, from counterflow experiments [28] our droplets motion model is expected to be valid for $St \lesssim 0.1$.

2.2. General spray-flamelet structure

130 The spray-flamelet equations follow the formulation derived in [10] for counterflow gaseous flames, but accounting for a vaporisation source term due to the presence of droplets. We perform a coordinate transformation $(x_1, x_2, x_3) \rightarrow (\xi(x_1, x_2, x_3), \xi_2, \xi_3)$. This new coordinate system is attached to the flame element, with ξ being the coordinate normal to the flame, and ξ_2, ξ_3 mutually orthonormal tangential components. In this coordinate system, the derivatives

135 along the ξ -direction are much larger than in the ξ_2 - and ξ_3 -directions, which yields for mass, momentum, mixture fraction and energy conservation:

$$\sqrt{\frac{\chi}{2D}} \frac{d}{d\xi} (\rho u_i) = \alpha_0 S_v, \quad (13a)$$

$$\sqrt{\frac{\chi}{2D}} \frac{d}{d\xi} (\rho u_i u_j) = \mu \frac{Pr}{Pe} \sqrt{\frac{\chi}{2D}} \frac{d^2 u_j}{d\xi^2} + \Sigma_\xi^* \frac{du_j}{d\xi} - J_j \frac{dp}{d\xi} + \alpha_0 S_v u_{lj} - g_j, \quad (13b)$$

$$\sqrt{\frac{\chi}{2D}} \frac{d}{d\xi} \left(\rho u_i \int L(Z) dZ \right) = \frac{\rho \chi}{2} \frac{d^2 Z}{d\xi^2} + \Sigma_\xi^\dagger \frac{dZ}{d\xi} + \frac{S_v}{1+\phi}, \quad (13c)$$

$$\sqrt{\frac{\chi}{2D}} \frac{d}{d\xi} (\rho u_i H_N) = \frac{\rho \chi}{2} \frac{d^2 H}{d\xi^2} + \Sigma_\xi^\dagger \frac{dH}{d\xi} + \frac{S_h}{1+\phi}, \quad (13d)$$

where

$$\Sigma_\xi^* = \frac{1}{2} \frac{Pr}{Pe} \mu \frac{d}{d\xi} \left(\frac{\chi}{2D} \right) + \frac{\chi}{2D} \frac{d}{d\xi} \left(\frac{Pr}{Pe} \mu \right), \quad \Sigma_\xi^\dagger = \frac{1}{2} \frac{\Gamma \gamma}{Pe} \frac{d}{d\xi} \left(\frac{\chi}{2D} \right) + \frac{\chi}{2D} \frac{d}{d\xi} \left(\frac{\Gamma \gamma}{Pe} \right), \quad (14)$$

are generalised fluxes, and

$$\chi = 2D \frac{\partial \xi}{\partial x_i} \frac{\partial \xi}{\partial x_i}, \quad (15)$$

is the generalised scalar dissipation rate [10] and $J_j = \partial \xi / \partial x_j$ [7].

Finally, the coordinate transformation to ξ -space for the liquid phase leads to

$$\sqrt{\frac{\chi}{2D}} \frac{d}{d\xi} (f_l \rho_l u_{li}) = -\alpha_O S_v, \quad (16a)$$

$$u_{lj} = u_j - a^2 St \sqrt{\frac{\chi}{2D}} \left(u_i \frac{du_j}{d\xi} \right), \quad (16b)$$

$$\sqrt{\frac{\chi}{2D}} \frac{d}{d\xi} (f_l \rho_l u_{li} T_l) = -\alpha_O S_v [T_l - \tilde{c} \nu (q + L_v)]. \quad (16c)$$

140 The set of Eqs (13)–(16) define the generalised spray-flamelet equations in ξ -space, with constant but non-unity Lewis numbers and accounting for temperature and velocity differences for the liquid phase.

145 In the next Section we will show the choice of the function ξ that naturally leads to a monotonic description of the spray-flamelet equations for a counter-flow configuration.

3. Strictly monotonic Cumulative Mixture Fraction Function Z_C

The proposed approach is to define a new coordinate Z_C as the integral of the mixture fraction Z along η , which is an integration variable parallel to ξ .

Figure 1: Schematic of the coordinate systems considered: x_i are the laboratory coordinates; ξ_i are the flame-attached coordinates, with η parallel to the normal coordinate along the flame, ξ .

Since Z_C is integrated along the parallel direction of ξ , we thereby guarantee that it is also parallel to the flame surface. This allows us to choose Z_C as the generic variable ξ and to write $d\eta = (\partial\eta/\partial x_i)dx_i$. A schematic of the coordinate systems considered in this work is shown in Fig. 1. Note that although ξ and η are parallel, they are not the same variable. The following coordinate transformation can thus be written:

$$\xi(\eta) = Z_C(\eta) = \frac{1}{Z_C^T} \int_{-\infty}^{\eta} \frac{e^{-s^2/2}}{\sqrt{2\pi}} Z(s) ds, \quad Z_C^T = \int_{-\infty}^{\infty} \frac{e^{-s^2/2}}{\sqrt{2\pi}} Z(s) ds. \quad (17)$$

In particular, we have that

$$\frac{dZ_C}{d\eta} = \frac{e^{-\eta^2/2}}{\sqrt{2\pi}} \frac{Z(\eta)}{Z_C^T}, \quad (18)$$

which enables the calculation of Z_C^T and the conversion back to η -space

$$Z_C^T = \frac{\int_{-\infty}^{\infty} e^{-\eta^2/2} d\eta / \sqrt{2\pi}}{\int_0^1 dZ_C / Z(Z_C)}, \quad \eta = Z_C^T \int_0^{Z_C} \sqrt{2\pi} e^{\eta^2/2} \frac{dZ'_C}{Z(Z'_C)}. \quad (19)$$

Notably, this choice enables us to find a closure relation for the dissipation rate as

$$\frac{\chi}{2D} = \left(\frac{dZ_C}{dx_i} \right)^2 = \frac{\chi_\eta}{2D} \left(\frac{\partial\eta}{\partial x_i} \right)^2, \quad \frac{\chi_\eta}{2D} = \frac{e^{-\eta^2}}{2\pi} \left(\frac{Z(\eta)}{Z_C^T} \right)^2 \quad (20)$$

Note that this definition differs from [10] in which $\xi = Z$ is used as independent variable: $\chi_Z = 2D(dZ/dx_i)^2$. Moreover, it is possible to obtain an expression for χ defined in Eq. (20),

$$\frac{\chi}{2D} = \left(\frac{dZ_C}{d\eta} \frac{d\eta}{dZ} \frac{dZ}{dx_i} \right)^2 = \left(\frac{1}{Z_C^T} \frac{e^{-\eta^2/2}}{\sqrt{2\pi}} Z(\eta) \right)^2 \left(\frac{d\eta}{dx_i} \right)^2, \quad (21)$$

its dependence on the spatial transformation $d\eta/dx_i$ is readily seen.

Using (20) in Eqs. (13) yields:

$$\sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \frac{d}{dZ_C} (\rho u_i) = \alpha_0 S_v, \quad (22a)$$

$$\sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \frac{d}{dZ_C} (\rho u_i u_j) = \mu \frac{Pr}{Pe} \sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \frac{d^2 u_j}{dZ_C^2} + \Sigma_\xi^* \frac{du_j}{dZ_C} - J_j \frac{dp}{dZ_C} + \alpha_0 S_v u_{lj} - g_j, \quad (22b)$$

$$\sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \frac{d}{dZ_C} \left(\rho u_i \int L(Z) dZ \right) = \rho D \frac{\chi_\eta}{2D} \left(\frac{\partial \eta}{\partial x_i} \right)^2 \frac{d^2 Z}{dZ_C^2} + \Sigma_\xi^\dagger \frac{dZ}{dZ_C} + \frac{S_v}{1+\phi}, \quad (22c)$$

$$\sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \frac{d}{dZ_C} (\rho u_i H_N) = \rho D \frac{\chi_\eta}{2D} \left(\frac{\partial \eta}{\partial x_i} \right)^2 \frac{d^2 H}{dZ_C^2} + \Sigma_\xi^\dagger \frac{dH}{dZ_C} + \frac{S_h}{1+\phi}, \quad (22d)$$

where

$$\begin{aligned} \Sigma_\xi^* &= \frac{1}{2} \frac{Pr}{Pe} \mu \frac{d}{dZ_C} \left[\frac{\chi_\eta}{2D} \left(\frac{\partial \eta}{\partial x_i} \right)^2 \right] + \frac{\chi_\eta}{2D} \left(\frac{\partial \eta}{\partial x_i} \right)^2 \frac{d}{dZ_C} \left(\frac{Pr}{Pe} \mu \right), \\ \Sigma_\xi^\dagger &= \frac{1}{2} \frac{\Gamma^\gamma}{Pe} \frac{d}{dZ_C} \left[\frac{\chi_\eta}{2D} \left(\frac{\partial \eta}{\partial x_i} \right)^2 \right] + \frac{\chi_\eta}{2D} \left(\frac{\partial \eta}{\partial x_i} \right)^2 \frac{d}{dZ_C} \left(\frac{\Gamma^\gamma}{Pe} \right). \end{aligned} \quad (23)$$

150 Similarly, Eqs. (16) become

$$\sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \frac{d}{dZ_C} (f_l \rho_l u_{li}) = -\alpha_O S_v, \quad (24a)$$

$$u_{lj} = u_j - a^2 St \sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \left(u_i \frac{du_j}{dZ_C} \right), \quad (24b)$$

$$\sqrt{\frac{\chi_\eta}{2D}} \frac{\partial \eta}{\partial x_i} \frac{d}{dZ_C} (f_l \rho_l u_{li} T_l) = -\alpha_O S_v [T_l - \tilde{c}\nu(q + L_v)]. \quad (24c)$$

Essentially, this formulation depends on the relation between the locally normal flame coordinate η and the physical coordinate x_i through the derivatives $d\eta/dx_i$. It is worth emphasizing that using the spray-flamelet formulation just derived in multidimensional numerical simulations of turbulent diffusion flames would then entail the implementation of the $d\eta/dx_i$ relation in each flamelet.

In the next Section, we highlight the main features of this new mathematical framework by considering a planar counterflow configuration.

4. Results and Discussion

160 A schematic of the case setup is included in Fig. 2, whose main assumption is a constant density ($\rho = 1$), monodisperse fuel spray. If we additionally consider $t_c = A^{-1}$ as the characteristic time scale with A being the strain rate, the flow

field is described in its dimensionless form as a potential flow $\mathbf{u} = (-x_1, x_2)$, in physical x_i -space i.e., (x_1, x_2) .

165 For this particular configuration, where the flow is aligned with the x_1 -axis, $d\eta/dx_1 = 1$. Furthermore, note that the choice of a potential flow implies that the droplets do not disturb the gaseous flow field (this is analogous to assuming that the liquid volume fraction is negligible, i.e., $n_l V_l = f_l \ll 1$) which in turn implies that the drag force $g \sim n_l V_l$ in Eq. (22b) can be neglected.

170 Upon applying the simplifications mentioned above, the system of equations for the gaseous phase becomes

$$\sqrt{2\pi}e^{x^2/2} \left[x \frac{\Gamma^\gamma}{Pe} \frac{dZ}{dZ_C} - \frac{d}{dZ_C} \left(x \int L(Z) dZ \right) \right] - \frac{d}{dZ_C} \left[\frac{\Gamma^\gamma}{Pe} \frac{Z}{Z_C^T} \frac{dZ}{dZ_C} \right] = \frac{2\pi e^{x^2} S_v}{1 + \phi} \frac{Z_C^T}{Z}, \quad (25a)$$

$$\sqrt{2\pi}e^{x^2/2} \left\{ x \frac{\Gamma^\gamma}{Pe} \frac{dH}{dZ_C} - \frac{d}{dZ_C} (x H_N) \right\} - \frac{d}{dZ_C} \left[\frac{\Gamma^\gamma}{Pe} \frac{Z}{Z_C^T} \frac{dH}{dZ_C} \right] = \frac{2\pi e^{x^2} S_h}{1 + \phi} \frac{Z_C^T}{Z}. \quad (25b)$$

where $x = x_1$ only, because the variations along x_2 are small.

The boundary conditions for Eqs. (25) are given by

$$\begin{aligned} Z = 1, \quad H &= [\Theta_{-\infty} + (Q - 1)\phi]/(1 + \phi), & \text{for } Z_C \rightarrow 0, \\ Z = 0, \quad H &= (\Theta_\infty + 1)/(1 + \phi), & \text{for } Z_C \rightarrow 1. \end{aligned} \quad (26)$$

Figure 2: Spray-flamelet model with fuel injected from the left and air from the right side. Left: Schematic of canonical problem considered. Right: Close up to flame region. Reproduced from [19].

Using Eq. (11) the velocity of the droplets is

$$u_l = -x(1 + a^2 St), \quad (27)$$

Additionally, the droplets are injected at its boiling temperature T_B , which eliminates the energy equation for the droplets in the governing equations, i.e. Eq. (16c).

The model for the vaporisation of droplets is modified from [19] to account for the gas-liquid relative motion. The source term can then be written as

$$S_v = M\lambda_{ef}, \quad M = \frac{3Le_O\nu}{Y_{O\infty}} \frac{f_l\rho_l}{a^3} (1 + a^2St). \quad (28)$$

where $\lambda_{ef} = \lambda(x)/(1 + a^2St)$. More details are included in Appendix 7.

Two liquid fuels are considered, ethanol (C_2H_6O) and methanol (CH_4O) for the spray in the simulations, whose chemical heat release, latent heat, boiling temperature and mass density (at its boiling temperature) are presented in Table 1. The remaining parameters are: $\gamma = 0$, $\bar{Y}_{O\infty} = 0.21$, $\phi = Le_O/Le_F$, $\bar{c}_p = 1.0$ kJ/kg K, $\bar{T}_{-\infty} = 300$ K, $\bar{T}_{\infty} = 400$ K, $\bar{\rho}_{\infty} = \bar{\rho}_{air} = 0.88$ kg/m³ and $f_l = 5 \times 10^{-4}$; Eq. (28), yields $M = 10$ and 14 for CH_4O and C_2H_6O , respectively.

Table 1: Fuel properties.

Fuel	ν	Q (kJ/g)	l (kJ/g)	T_B (K)	$\bar{\rho}_l$ (kg/m ³)	M
CH_4O	1.5	22.3	1.18	338	792	10
C_2H_6O	2.087	29.7	0.846	351	789	14

The following global stoichiometric reactions are used

The system of integro-differential equations (25) were discretized using finite volumes. Adaptive mesh refinement, based on the temperature gradient, was used to ensure adequate resolution of the spray-flame structure. For the discretization of the diffusive and convective terms a second order central difference scheme and a first order upwind interpolation (to avoid spurious oscillations near the flame) were implemented, respectively. All simulations were performed using a pseudo-transient approach to better control the numerical stability of the solution [29].

To solve Eqs. (25) an iterative algorithm was developed using the following methodology. First, with an initial condition for Z , a first guess for Z_C^T was calculated by Eq. (17) using an adaptive trapezoidal integration rule based on the computational mesh in x -space (with an initial size of 10^4 nodes). Second, with Z_C^T , a first prediction to the solution of the system (25) was determined. Third, a new guess to Z_C^T can be computed with the predicted values of H and Z , again, with Eq. (17). This procedure was repeated until predicted and corrected values for Z_C^T , Z and H converged to an L_1 -norm within 10^{-10} .

The profiles of Z and Z_C are shown in Fig. 3. The solution in physical space is shown by solid black lines and the corresponding reference solution obtained using the Z_C -space formulation mapped to x -space is shown by red dashed lines. The relative deviation between both profiles is less than 10^{-6} over the entire domain. Figure 3(a) shows that the mixture fraction Z , a monotonic

variable in purely gaseous flows, is no longer monotonic in a model that includes evaporating droplets in liquid phase. Z_C , on the other hand, remains single-valued as seen in Fig. 3(b).

Results for $Le = 1$, and $St = 0$ are presented in subsection 4.1 to highlight the main strengths of the proposed formulation. Subsections 4.2 and 4.3 show the effects of non-unity Lewis numbers, and variation of the Stokes number (i.e. $St < 0.1$) on the spray-flame structure.

Figure 3: (a) The mixture fraction Z and (b) the cumulative mixture fraction Z_C of ethanol in terms of physical space x . The generic variable Z_C is a monotonic function of x , which is not the case for Z usually adopted in gaseous flows. The solution in physical space is shown by lines and the corresponding reference solution from the Z_C -space formulation converted back to the x -space is shown by open circles.

4.1. Unity Le and zero St

All results, from here on, were obtained in Z_C -space and subsequently mapped to x -space for clarity, unless specified otherwise. Fig. 4 shows profiles of Y_F , Y_O , Θ , Z and H . The flame position is characterised by $Y_O = Y_F = 0$ which expectedly coincides with the location where the temperature is highest. The peak observed in the mass fractions is due to the vaporisation of the droplets since it is a source of mass. A few things are worth mentioning from these plots: (i) C_2H_6O has a lower latent heat of vaporisation than CH_4O , as a result its mass fraction reaches higher values; (ii) Additionally, C_2H_6O has a higher heat of combustion than CH_4O which leads to a higher flame temperature than for CH_4O ; (iii) The flame achieves stoichiometric conditions further into the oxidant side for C_2H_6O than for CH_4O , this is due to the higher fuel content for the former.

The droplet radius and evaporation rate spatial distributions are presented in Fig. 5, as in [19]. The droplet radius is initially constant, and decreases as it approaches the flame until the droplet is fully vaporised (see Fig. 5 (a)). The vaporisation extends further for CH_4O than for C_2H_6O (i.e. $a = 0$ at $x = -0.38$

230 and $x = -0.47$, respectively.) Fig. 5 (b), is in line with the result obtained for
the droplet radius, since the evaporation rate, λ , is non-zero only in the region
where the droplets are present.

To highlight the value of the cumulative mixture fraction, Z_C , proposed
in this work, Fig. 6 shows a comparison of the profiles of mass fractions and
235 temperature in Z and Z_C -space. The profiles in Z -space for each fuel have
the same linear dependence as that given from its definition at stoichiometric
conditions $Z = (1 + Y_F - Y_O)/2$, valid for unity Lewis numbers. The maximum
value of Z attained for each fuel differs (see red dashed line and solid black line),
as these values are a function of the vaporisation rate.

240 Close inspection of Fig. 6, shows that for $Z > 1$, the mass fractions and
temperature profiles are multivalued. Note that in contrast with pure gas flow
whose maximum value is bounded at $Z = 1$, here Z extends beyond unity.
The non-monotonicity for the Y_F variable occurs along the same straight line
and thus, it is not visible at this scale in Fig. 6. The numbered annotations in
245 Fig. 6 correspond to the path taken by the fuel stream in the Z -space, from

Figure 4: Mass fractions (Y_F , Y_O), temperature (Θ/Θ_∞), mixture fraction (Z) and excess of enthalpy (H) profiles in the physical space x . The peak observed in the profiles of Y_F , Y_O , Z and H is due to the vaporisation source. The flame position around $x_f = 0.8$ separates the fuel region at left ($Y_O = 0$) from the oxidiser side at right ($Y_F = 0$).

Figure 5: (a) Droplet radius a and (b) vaporisation rate λ , which is non-zero only in the region where droplets vaporise.

injection until it reaches the flame. At position 1 ($Z = 1$) the fuel droplets are injected in the gaseous fuel stream. The vaporisation of droplets increases the value of Y_F to a maximum, different for each fuel (see position 2). From point 2 to 3, consumption of fuel by the flame decreases the value of Y_F , from its maximum at point 2 to zero at point 3. From the description above, it is evident that Z is not an adequate function that guarantees that both Y_F and Θ be uniquely defined, as the trajectories taken by the fuel mass fraction and temperature profiles (path 1 – 2 – 3) are non-monotonous in Z -space. For clarity, path 1 – 2 – 3 is also shown in Fig. 4 in physical space, x . Finally, it is worth reiterating that remapping the solution to physical space, x , would not be possible due to the multivalued nature of the formulation in Z -space.

Figure 6 also shows the profiles of mass fractions and temperature as a function of Z_C ; profiles of Z and H are also shown for completeness. In this space, $Z_C = 0$ corresponds to the fuel stream whereas $Z_C = 1$ represents the oxidant stream. The flame position ($Y_O = Y_F = 0$) can be identified by searching for the value of Z_C where the normalised temperature, Θ/Θ_∞ , reaches its maximum value. These results show clearly that the variables are single-valued in the Z_C -space and that Z_C is a useful space for the spray-flamelet description.

It must be emphasised that the profiles do not show over- or under-estimated values of temperature, regardless of the droplet radius or strain rate, which is accounted for through M . This is an advantage over [7] where the temperature is overestimated for the highest values of the strain rate due to the assumed closure relation for χ . In the present work, this is not the case because χ can be directly evaluated from the formulation, as seen in Eq. (21).

Finally, the comparison of the scalar dissipation rate, $\chi = (dZ_C/dx)^2$, and that obtained using Z as the generic variable, $\chi_Z = (dZ/dx)^2$ [10], are shown in Fig. 7. Since in the present case the flow is aligned with the physical axis, such that $d\eta/dx = 1$, the closed-form expression for the scalar dissipation rate

Figure 6: mass fractions (Y_F , Y_O) and temperature profiles (Θ/Θ_∞) as a function of the mixture fraction Z (Top). For $Z > 1$, which corresponds to the peak of the vaporisation zone in Fig. 4, Y_F nor Θ are uniquely defined, showing the non-monotonic behaviour in the Z -space description of the problem. Annotations: 1: beginning of vaporisation in the fuel side ($Z = 1$), 2: maximum in vaporisation rate (maxima in Y_F and Z), 3: flame position ($Y_F = Y_O = 0$), 4: incoming flow oxidant side ($Z = 0$); Mass fractions (Y_F , Y_O) and temperature profiles (Θ/Θ_∞) (Middle), mixture fraction (Z) and excess of enthalpy (H) (Bottom) in the Z_C -space for $Le_F = Le_O = 1$. Note that the temperature and the mass fraction are uniquely defined in this space, as opposed to when they are defined in the Z -space.

χ in space Z_C is obtained from Eq. (21) as

$$\chi = 2D \left(\frac{1}{Z_C^T} \frac{e^{-\eta^2/2}}{\sqrt{2\pi}} Z(\eta) \right)^2. \quad (29)$$

270 In agreement with Eq. (29), Fig. 7 shows that χ increases smoothly, reaches a maximum value and then decreases almost symmetrically. In contrast, χ_Z exhibits a more complex behavior (see Fig. 7 (b)), these shapes can be understood by inspecting Eq. (29) and recalling the results presented in Fig. 3: the maximum value of Z explains why there is a region where χ_Z goes to zero; 275 the profile of Z_C as a function of x has an inflection point responsible for the maximum value observed in profiles shown for χ .

Figure 7: The scalar dissipation rate for sprays (a) $\chi = (dZ_C/dx)^2$ and (b) $\chi_Z = (dZ/dx)^2$ using Z_C and Z respectively as the generic variable. χ_Z is the definition typically considered for purely gaseous flow.

4.2. Non-unity Le_F and Le_O

Table 2: Lewis numbers.		
O_2	CH_4O	C_2H_6O
1.06	1.25	1.73

280 In this section we briefly assess the effect of non-unity Le numbers in the spray-flamelet structure. The Le numbers used in the simulations are presented in Table 2. These were determined using Cantera [30], and CaltechMech [31]. Profiles of Y_F , Y_O , Θ , and Z in Z_C -space, are shown in Fig. 8 for both fuels C_2H_6O and CH_4O . The profiles show quantitative differences when compared with the unity Le number results (solid lines); these differences are more evident for C_2H_6O , which has a higher Le_F than CH_4O . While the differences in Θ and

Z do not seem to be as pronounced for both fuels, the mass fractions show a more significant variation. Also, the flame position sensitivity increases with increasing Le .

Figure 8: Comparison between the results with unitary and correct values of the Lewis numbers for (a) C_2H_6O (ethanol) and (b) CH_4O (methanol)

A Le number increase results in enhanced heat transfer with respect to mass

diffusion. Consequently, higher values of Le result in improved heat removal
 290 from the flame towards the cold reactants sides. The decrease on the flame
 temperature leads to a decrease on the vaporisation rate, and thus to smaller
 values of the gaseous fuel content, Y_F , on the fuel side. The lower gaseous
 fuel content yields a flame that attains stoichiometric conditions further into
 the fuel side, as seen in Fig. 8. Note that this behaviour is the same for both
 295 fuels, since both have Lewis number greater than unity. Additionally, χ_Z and χ
 profiles in x -space are shown in Fig. 9. Both scalar dissipation rates, χ_Z and χ ,
 represent the inverse of the characteristic mass diffusion time [10], consequently
 an increase in the Lewis number directly translates into higher χ_Z and χ values
 (see Fig. 9).

Figure 9: Comparison of χ and χ_Z between unity Le and constant but non-unity Le results for (a) C_2H_6O (ethanol) and (b) CH_4O (methanol).

300 4.3. The effect of varying St

The results presented in this section were obtained using the same set of
 parameters as in the previous subsection but for Stokes number varying from
 $0 \leq St \leq 0.1$, its limit value according to Eq. (12).

In Figs. 10 and 11, the influence of the Stokes number St on the flame position, x_f , flame temperature, Θ_f , droplet radius, a , and the scalar dissipation rate, χ , are shown. a and χ are presented in physical space as it provides a more intuitive picture with $x < 0$ being the fuel region, and $x > 0$ being the oxidant region. An increase on the Stokes number St is equivalent to having a larger initial droplet size. Since we assume complete combustion, this leads to more fuel reaching the flame, whose end result is that the flame is pushed towards the oxidant side and its temperature increases. These effects are clearly seen in Figs 10 (a) and (b), respectively.

Figure 10: (a) Flame position x_f and (b) flame temperature Θ_f as function of the Stokes number for ethanol ($Le = 1.73$) and methanol ($Le = 1.25$) with $Le_O = 1.06$

Note that the droplets vaporize completely prior to reaching the flame (compare Figs. 10(a) and 11(a)) because of the assumption of complete combustion; if it were to be relaxed, unvaporized droplets may reach the flame, leading to heat removal from the reaction zone and a subsequent decrease in flame temperature [32]. Furthermore, if the droplets cross over the stagnation plane towards the incoming oxidant stream, they are subsequently brought back towards the fuel side. This flow behavior may lead to oscillations in the flame front, destabilising the flamelet, as discussed in [33]. Finally, if two-way coupling were to be considered, i.e., that the droplets also affect the gaseous flow field, an increase in St would push the flame even further towards the oxidant side due to droplets inertia [34].

We emphasise that a more realistic evaluation of the influence of the Stokes number in the problem at hand, would unavoidably require accounting for two-way coupling. This is nonetheless left for a future investigation. In the present case, where potential flow was assumed (i.e., the liquid phase does not influence the gaseous phase), changes in St are only brought about through the droplet radius, see Eq. (34) in the Appendix. This effect is small, as seen in Fig. 11 (a), where the spatial distribution of the droplet radius, a , for three values of St

Figure 11: Profiles of the (a) droplet radius a and (b) dissipation rate χ for different values of the Stokes number for ethanol ($Le = 1.73$) with $Le_O = 1.06$. The droplets vaporise completely prior to reaching the flame.

is shown. Since the gas flow field is not affected by the droplets, the changes in the scalar dissipation rate, χ , as a function of St are also small, as seen in Fig. 11 (b). While the results in Fig. 11 are only shown for C_2H_6O , those for CH_4O show the same trends.

5. Conclusions

The cumulative mixture fraction variable, Z_C , was proposed for the description of the spray-flamelet structure in a counterflow configuration accounting for variable Le and St numbers. The flamelet formulation was derived and the feasibility of directly integrating the resulting spray-flamelet equations in Z_C -space was demonstrated. Our results show that in contrast to the traditionally used variable for flamelet description, $Z(x_i)$, the cumulative mixture fraction, $Z_C(x_i)$, is a monotonic function, allowing temperature, $\Theta(Z_C)$, and mass fractions, $Y_O(Z_C)$ and $Y_F(Z_C)$, to be uniquely defined in this space. Similarly, the scalar dissipation rate, χ , defined in terms of Z_C was also shown to be a smooth function in physical space x . Notably, a closure relation is not required to describe its behaviour because it can be directly obtained from the proposed Z_C -space formulation. The influence of fuel effects, through their Le numbers, and droplet size, through variations in St numbers, were analyzed. The spray-flamelet structure was found to be sensitive to increasing Le , with the flame stabilizing earlier towards the fuel side. In contrast, increasing St favored stabilization towards the oxidant side. These observations are in line with the expected physical behavior. Future work will include testing our formulation as a subgrid model in multi-phase and multi-component turbulent flows.

7. Appendix - Vaporisation model

The model for the vaporisation of isolated droplets was developed in a previous work for $St = 0$ [19], and here we extend it to account for $St \neq 0$. For the liquid phase with constant liquid density $\bar{\rho}_l$ we only need to solve for the total mass of liquid [35]

$$\frac{\partial}{\partial x_i}(n_l \rho_l V_l u_{li}) = -\alpha_O S_v. \quad (30)$$

If we consider that the spatial variation of the droplets volume is much larger than the variation in its velocity, i.e., $n_l \rho_l u_{li} \partial V_l / \partial x_i \gg V_l \partial (n_l \rho_l u_{li}) / \partial x_i$, Eq. (30) becomes

$$n_l \rho_l u_{li} \frac{\partial}{\partial x_i} V_l = -\alpha_O S_v. \quad (31)$$

For the 1-D potential flow with spherical droplets

$$u_l = -x(1 + a^2 St), \quad V_l = \frac{4\pi}{3} a^3, \quad (32)$$

such that the droplets mass conservation is given by

$$x \frac{da^3}{dx} = -3\lambda_{ef}, \quad \lambda_{ef} = \frac{\lambda(x)}{1 + a^2 St} = \frac{\alpha_0 S_v}{4\pi n_l \rho_l (1 + a^2 St)} \quad (33)$$

in which λ is the vaporisation rate. Defining the vaporisation function $\beta = \lambda/a$ and integrating Eq. (30), the droplet radius is given by the nonlinear relation

$$a^2 \left(1 + \frac{a^2}{2} St \right) = \left[1 + \frac{St}{2} + 2 \int_{-\infty}^x \frac{\beta(s)}{s} ds \right] \mathcal{H}(T - T_B), \quad (34)$$

in which $\mathcal{H}$ is Heaviside function. The vaporisation function $\beta(x)$ depends on the ambient temperature and on the temperature of the droplet (in our case, the liquid fuel boiling temperature, T_B)[35]

$$\beta(x) = \int_{T_B}^{T_{l\infty}} \frac{dT}{T - T_B + L_v} = \ln \left(1 + \frac{T_{l\infty} - T_B}{L_v} \right), \quad (35)$$

The ambient temperature for the droplet, $T_{l\infty}$, corresponds to the local temperature in the spray problem. These expressions are obtained from the classical model for vaporisation of isolated droplets [35, 19]. From Eq. (33) and using $n_l = f_l / (4\pi a^3 / 3)$, the source term can be written as

$$S_v = M \lambda_{ef}, \quad M = \frac{3Le_O \nu}{Y_{O\infty}} \frac{f_l \rho_l}{a^3} (1 + a^2 St) \quad (36)$$

It is worth noting that the spray combustion parameter M combines properties of chemical reaction, flow field and spray [20]. This non-dimensional parameter permits the analysis of the influence of the initial droplet radius on the spray-flamelet structure by just varying M . Conveniently, the combustion process can be studied by analysing only this parameter and not the individual influence of each of its constituent parts.

Note that the vaporisation source term, S_v , does not depend on St (a consequence of considering a potential flow) and is zero for the following situations: i) $M = 0$ if the gas temperature not reached the boiling temperature yet, and ii) $\lambda = 0$ if the droplets are totally vaporised.
