Abstract

Aim: To develop a new nanostructured lipid carrier (NLC) co-loaded with doxorubicin and docosahexaenoic acid (DHA) for combination therapy to evaluate the *in vitro* activity in drug sensitive and resistant cancer cell lines.

Methods: The NLC was prepared by a hot homogenization method and they were characterized by size, zeta potential, entrapment efficiency and drug loading. The drug release was evaluated by dialysis in DMEM and NLC aggregation was assayed ~~for~~ **in the** presence of serum. The cytotoxicity of formulations and drug uptake were evaluated in a cell monolayer model with sensitive MDA-MB-231, MCF-7 and **maybe? the doxorubicin-resistant variant MCF-7/Adr as monolayers or spheroid cultures** the drug resistant MCF-7/Adr cell lines and in spheroids of MCF-7/Adr.

Results: The formulation obtained had a size of about 80 nm and a negative charge of zeta potential. The NLC loaded with doxorubicin and DHA showed the same activity as free drugs against MCF-7, slightly higher activity for MDA-MB-231 and much stronger activity against MCF-7/Adr. Maybe similar on sensitive, higher resistant? The doxorubicin uptake of free and encapsulated drug was similar for sensitive cell lines and higher for the resistant, suggesting a bypassing of the P-glycoprotein pump bomb efflux by NLC. For spheroids, the NLC loaded with doxorubicin and DHA showed stronger activity that may be explained by the greater penetration of the formulation into the spheroids structure and the combination of the respective drugs. The higher activity of NLC in spheroids was correlated with increased drug penetration than free doxorubicin? These findings suggest that the combination of doxorubicin and DHA improves of the drugs activity and that their co-encapsulation in NLC shows higher efficacy, being a promising alternative for cancer therapy in sensitive and resistant cell lines?.

1 Introduction

Doxorubicin is an anthracycline with broad-spectrum anticancer activity that is widely used in cancer therapy but has serious side effects highlighted by potentially fatal cardiotoxicity (Livi et al, 2009; Shi et al, 2011). The low tumor penetration and limited distribution in solid tumors are the main causes of its failures as a therapeutic agent (Primeau et al., 2005; Trédan et al., 2007) could add Lankelma doxorubicin gradients. Anthracycline-based combination chemotherapy regimens have shown ... Combination of anthracycline-based chemotherapy has shown improvement in activity compared to a single anthracycline, including combined doxorubicin or epirubicin with cyclophosphamide; doxorubicin, cyclophosphamide, and fluorouracil; epirubicin with cyclophosphamide and fluorouracil. However, despite greater activity, they these regimens are also more toxic than single agent regimens (Jassem et al, 2001; Livi et al, 2009).

Alternatively, the combination of docosahexaenoic acid (DHA) and doxorubicin has been described to increase the sensitivity of tumors to chemotherapy compared to the single doxorubicin (Germain et al. 1998; Colas et

al., 2006; Siddiqui et al., 2011). DHA is a long-chain (C22) polyunsaturated fatty acid (Omega 3) that enhances oxidative stress and subsequent lipid peroxidation of tumor cells (Mahéo et al, 2005). Several studies have reported an increase in the sensitivity of mammary tumors in rodents to doxorubicin when accompanied by a prolonged supplementation with DHA (Hardman et al., 2001; Colas et al., 2006;) and others have verified that this is probably due to the increased level of oxidative stress specifically in cancer cells (Hajjaji et al, 2012). In addition, the literature suggests that DHA attenuates drug resistance and improves anticancer drug efficacy in resistant cell lines (Mahéo et al, 2005; Siddiqui et al, 2011). Recently, a phase II trial verified that a dietary DHA supplementation improved the outcome of chemotherapy in metastatic breast cancer patients (Bougnoux et al., 2009). However, the varieties of drug administration schedules have complicated the management of the pharmacokinetic and pharmacodynamic profiles and the obtention of obtain a uniform temporal and spatial codelivery (co-delivery?) is challenging (Atu-027, CPX) practically impossible. Thus, the combination drugs using drug delivery systems (DDSs) emerges as an attractive alternative (Storniolo et al, 2008) (Parhi, nanotechnology-based combinatorial drug delivery?).

DDSs based on approaches in nanobiotechnology DDSs-based combination therapy? offer many advantages, such as more synchronized and controlled pharmacokinetics of the drugs, resulting in improved drug efficacy, with a single formulation with improved solubility and bioavailability, with a predominantly endocytotic uptake and the potential to bypass mechanisms of multidrug resistance (Okuda and Kidoaki, 2012). Among these DDSs, liposomes, polymeric micelles, solid lipid nanoparticles (SLNs), nanostructured lipid carrier (NLC) have been described. Some DDSs have reached the market, e.g. liposomal doxorubicin. Such nanocarriers with sizes in a range 50-200 nm enhance the concentration of drugs in the tumor by a mechanism known as the “enhanced permeability and retention (EPR) effect” (Maeda et al. 2000; Torchilin, 2011; Li et al., 2012).

The current NLC represent an improved generation of SLNs that consist of solid lipid matrices with spatially distributed liquid lipids, resulting in a structure with imperfections in the crystal structure that accommodate the drug. NLC and SLN? They share advantages including biocompatibility and the possibility of production

on an industrial scale since they do not require the use of organic solvents and their similarity to parenteral nutrition manufacturing methods. **Contrary to nanoemulsions, the drug release from NLC can be finely tuned by the nature of matrix liquid lipids?** Additionally, NLC is **are** capable of control the release that nanoemulsions can not offer due to their nature of matrix liquid lipids (Mehnert and Mäder, 2001; Müller et al., 2002; Wissing et al., 2004). However, the entrapment of hydrophilic drug, such as doxorubicin, in these lipid systems is usually low. The formation of an ion pairing with a lipophilic contra-ion has been proposed as an alternative to increase the drug encapsulation (Serpe et al. 2004; Wong et al., 2006; Mussi et al, 2013).

In this work our aim was to develop a new lipid formulation loaded with doxorubicin combined with DHA triglyceride (lipid liquid) as **a means** an alternative to obtain a NLC with enhanced doxorubicin activity, evaluate the formulation physicochemical characteristics, drug release and the *in vitro* efficacy in sensitive and resistant human breast cancer cell lines in cell monolayer and spheroid models.

2 Materials and Methods

2.1 Materials

Doxorubicin hydrochloride was purchased from ACIC Chemicals (Ontario, Canada). Doxorubicin hydrochloride liposome injection (Lipodox[®]) was purchased from Sun Pharma Global FZE (Gujarat, India). Triethanolamine (TEA), oleic acid (OA), ethylenediamine tetraacetic acid sodium (EDTA) were purchased from Sigma-Aldrich (Missouri, USA). Glyceryl behenate (Compritol 888 ATO[®]) was kindly provided by Gattefossé (Rhône-Alpes, France). Monooleate of sorbitan ethoxylated (Super refined[™] polysorbate 80; Tween[™] 80) and docosahexaenoic acid (DHA) as triglyceride (Incromega[™] DHA 500TG) were kindly provided by Croda Inc. (New Jersey, USA). Dulbecco's Modified Eagle Medium (DMEM), antibiotic stock solution (10,000 I.U. of penicillin + 10,000 µg/mL of streptomycin) and 0.25% Trypsin-EDTA were purchased from CellGro (Virginia, USA). Heat inactivated fetal bovine serum (FBS) was purchased from Atlanta Biologicals

(Georgia, USA). The Cell Titer Blue assay kit and CytoTox 96® Non-Radioactive Cytotoxicity Assay were purchased from Promega (Wisconsin, USA). All other chemicals were of analytical grade.

2.2 Preparation of formulation

The formulation was prepared by the hot melting homogenization method using emulsification-ultrasound and the composition was described previously with some modifications (Mussi et al., 2013). The DHA was used in triglyceride form (Incromega® DHA 500 TG). The formation of an ionic pairing to promote the doxorubicin encapsulation was obtained with oleic acid. Briefly, for a batch of 10 ml of formulation, the oily phase (OP) was prepared with 100 mg of Tween 80, 10 mg of oleic acid, 5 mg of doxorubicin, 6 mg of triethanolamine and 150 mg of matrix lipid composed of 110 mg of Compritol and 40 mg of DHA (0.4% w/v). The aqueous phase (AP) was composed of 4 mg of EDTA and 6 mL of purified water. This formulation was named NLC-DHA 0.4%. A control NLC was prepared loading doxorubicin and a liquid lipid with low amount of unsaturated lipids (peanut oil) at 0.4%. After the preparation the volume was adjusted to 10 mL using a volumetric cylinder. First, the OP and the AP were heated separately to 80°C. After OP melting at 80°C, the AP was gently dropped into the OP and homogenized using a glass rod for 1 min. This emulsion was immediately subjected to high intensity probe sonication (8 watts) for 5 minutes, using a high intensity ultrasonic processor (Fisher F60 Sonic Dismembrator Fisher F-6; Fisher Scientific, Pennsylvania, USA). The pH was adjusted to 7.0 with 0.1M HCl and 0.1 M NaOH. The formulation was stored at 4°C, protected from light **under** in a nitrogen atmosphere. To evaluate the influence of the lipid matrix on the release of doxorubicin, two additional formulations loaded with doxorubicin were prepared: NLC containing DHA at 0.8% (NLC-DHA 0.8%) and a nanoemulsion (NE) containing only 1.5% DHA as the lipid matrix (NE-DHA 1.8%).

2.3 Characterization of the formulations

The mean particle diameter and zeta potential were measured by dynamic light scattering (DLS) and electrophoretic mobility, respectively, using the Zeta

PLUS particle size analyzer (Brookhaven Instruments; Brookhaven, USA). All measurements were performed in triplicate.

The encapsulation efficiency (EE) and drug loading (DL) of doxorubicin in NLC were determined by an ultrafiltration method using centrifugal devices (Amicon® Ultra - 0.5 mL 100 k; Millipore, USA) with the membrane passivated with a 5% aqueous solution of Tween™ 20 to eliminate doxorubicin binding as previously described (Mussi et al., 2013). The EE and DL were calculated using the following equations:

$$EE(\%) = (C_T - C_{AP})/C_T \times 100$$

$$DL_{(mg/g)} = W_{DL}/W_{NP}$$

Where, C_T = total doxorubicin concentration in NLC, C_{AP} = doxorubicin concentration in aqueous phase (non-encapsulated), W_{DL} = mg of drug loaded in nanoparticles and W_{NP} = g of nanoparticles (lipids).

Briefly, the C_T , C_{AP} and W_{DL} were evaluated as follows. The C_T was analyzed dissolving an aliquot of the NLC dispersion in a mixture of tetrahydrofuran (THF)/methanol (MeOH) 4:6 v/v, centrifugation for 10 min at 2,400g and analysis of the supernatant by spectrophotometry at 480/x nm (UV-mini 1240; Shimadzu, Japan). The C_{AP} was evaluated from an aliquot of the aqueous phase separated from the NLC dispersion by ultrafiltration (10 min at 2,400g), dilution with THF/MeOH and analysis by UV-vis. The W_{DL} was calculated using the calculated EE x mg total of doxorubicin added.

2.4 Serum stability

Serum stability of NLC was investigated by incubating the NLC with FBS 1:1 at 37° C with shaking (250 rpm) for up to 24 h. Samples were collected, diluted in purified water and the measurement of zeta potential and size performed using the Zeta Plus Analyzer.

2.5 Release of doxorubicin from NLC

The release study was conducted by dialysis in DMEM containing 10% fetal bovine serum (adapted from Elbayoumi and Torchilin, 2008). Dialysis tubes with a cutoff size of 100 KDa (Cellulose ester membrane; Spectrum Laboratories; Rancho

Dominguez, USA) were filled with 3 mL of formulations loaded with doxorubicin or doxorubicin aqueous solution (0.5 mg/mL) diluted in the media 1:2, sealed and incubated with 50 ml of the media for up to 48 h at 37°C, with continuous shaking at 250 RPM. At various time points, aliquots were withdrawn, replaced with an equal volume of the media. The doxorubicin concentrations were measured by a spectrofluorimetric method using the Synergy HT Multi-Mode Microplate Reader (Biotek; Winnooski, USA) with 485/590 ex/em wavelengths. The values were plotted as percentage of **cumulative drug release** accumulated released drug.

2.6 Cell culture

MDA-MB-231 and MCF-7 were purchased from The American Type Culture Collection (ATCC; Manassas, USA) and MCF-7/Adr was obtained from The National Cancer Institute (Frederick, MD, USA). Cells were grown and maintained in DMEM, pH 7.4, supplemented with 10% (v/v) FBS and 1% of penicillin/streptomycin stock solution in a humidified, 5% (v/v) CO₂ atmosphere at 37°C.

2.7 Adherent monolayer cells

2.7.1 Cell viability

Cell viability was assayed with CellTiter Blue® Cell Viability Assay kit (CTB) following the manufacturer's protocol. MDA-MBA-231, MCF-7 and MCF-7/Adr were seeded in 96-well tissue culture plates at 5×10^3 /well about 24 h before the treatment. First, we evaluated the effect of a combination of free doxorubicin (1 μ M) and DHA at varying concentrations (9-562 μ M). The aqueous doxorubicin solution and ethanolic DHA (IncromegaTM E1050, Croda) solution were freshly prepared before the treatment. Second, we evaluated the cytotoxicity of the encapsulated drug compared to the free drugs with doxorubicin concentrations varying between 0.5-16 μ M and DHA between 3.5-112 μ M. For both experiments, the cells were incubated with the drugs for 24 h, after that washed thrice with complete DMEM, supplemented with 100 **mL**, followed by the addition of 20 μ L of the CTB reagent. The cells were incubated for 2 h and the fluorescence intensity

was measured using a Synergy HT Multi-Mode Microplate Reader with 530/590 ex/em wavelengths.

2.7.2 Doxorubicin uptake

The cellular uptake of doxorubicin by the cancer cells was assessed by flow cytometry by using the natural fluorescence of the drug. Cells were seeded in a 12 wells/plate at a density of 1×10^5 cells/well 24 h before the treatment. The seeding medium was removed and replaced by media containing 16 μ M of doxorubicin. After 2 hours incubation, the cells were washed thrice with PBS, trypsinized, centrifuged at 2000g for 5 min, suspended in PBS pH 7.4 and analyzed using a BD FACS Calibur flow cytometer. The cells were gated using forward (FSC-H) versus side-scatter (SSC-H) to exclude debris and dead cells before analysis of 10,000 cell counts. The mean fluorescence intensity (MFI) of the cells was measured at nm the FL-2 channel.

2.8 Spheroids

2.8.1 Preparation of spheroids

MCF-7/Adr were used to prepare spheroids of 400-500 μ m diameter, from 10,000 cells in 96 well/plates by a liquid overlay method according to Perche and Torchilin (2012), jcr if you want . Briefly, DMEM with 1.5% of agarose was pre-seeded in each well to prevent cell adhesion. After cell seeding, the plates were centrifuged for 15 min at 1,500 RCF. Spheroid formation was monitored using a Nikon Eclipse E400 microscope (Nikon Inc., Melville, USA) at 10 $\times$ magnification with a Spot Insight™3.2.0 camera with Spot Advanced™ software (Spot Imaging, Sterling Heights, MI).

2.8.2 Cytotoxicity

Cytotoxicity was measured with a Cytotox 96 Non-Radioactive Cytotoxicity kit (Promega; Fitchburg, USA) as reported by Perche and Torchilin (2012). Briefly, both the lactate dehydrogenase (LDH) released in the medium and the LDH from spheroids dissociated by incubation 1 h at 37°C with 0.9% Triton®-X100 in DMEM media with 10% FBS were measured. The amount of LDH released into the

medium after incubation with the treatments was calculated as a percentage in relation to the total (total LDH = medium LDH + lysate LDH).

2.8.3 Penetration of doxorubicin in spheroids

The distribution of free and encapsulated doxorubicin throughout the spheroids was evaluated by confocal microscopy. ~~was evaluated by the degree of penetration of the drug and whether the modification with NLC would improve it. The assessment was done~~ after 2 h of incubations with 100 μ M of doxorubicin in complete DMEM ~~by confocal microscopy~~ using 488 nm and 535 nm long pass filter for doxorubicin excitation/emission, respectively. The spheroids were removed from the plate, washed with PBS, placed into Lab-Tek chambers (Fisher Scientific) prior to imaging. They were visualized at 10x magnification, and the distribution of doxorubicin throughout the spheroids was analyzed with a Zeiss LSM 700 confocal microscope using Z-stack imaging with 10 μ m intervals and the LSM Image Browser software.

3 Results

3.1. NLC characterization

Table 1 lists the characterization data of the formulations for size, zeta potential, entrapment efficiency and drug loading. The sizes obtained were in the range of 76-86 nm with values of the polydispersity index (PDI) lower than 0.22. This suggested that they were monodispersed. The zeta potential was negative for all formulations and varied from -23 to -36 mV. The entrapment efficiency reached about 100%, and the drug loading was 31 mg/g. The others formulations (NLC-DHA 0.8% and NE-DHA 1.5%) showed very similar results for all of these characteristics (data not shown).

3.2. Drug release

The results of the drug release assay performed by dialysis with complete DMEM are included in Figure 1. (is 3mL vs 50 mL sink condition?) The released doxorubicin from NLC-DHA 0.4% was $5 \pm 1\%$ in the first 30 min and increased to $14 \pm 1\%$, $23 \pm 0\%$ and $30 \pm 1\%$ at 1 h, 2 h and 4 h, respectively. There was no

further release for up to 48 h. In contrast, for NLC-DHA 0.8% and NE-DHA 1.5%, the release at 30 min was $17 \pm 1\%$ and $17 \pm 2\%$, respectively and increased to more than 75% within 4 hours showing higher release of drug than NLC-DHA 0.4% for all evaluated points. The high release profiles of those two formulations were very similar and showed a lower capacity to retain the drug compared to the formulation with 0.4% of DHA. The free drug was evaluated as a control and within 2 hours more than 90% of doxorubicin was measured outside of the bag. Therefore, the formulation that was chosen to the next studies was NLC-DHA 0.4%.

3.3. NLC stability in serum

Considering the intended use (intravenous administration), the stability of NLC-DHA 0.4% in serum was investigated to check for aggregation in presence of proteins. The size, PDI and zeta potential are described in Table 2. Their size was around 70 nm after incubation with serum for up to 24 h. The variation of PDI was very small (in the range 0.15 to 0.18). The differences in zeta potential (-32 to -37 mV) were very small and not significant. Thus, the NLC-DHA 0.4% was very stable after incubation with serum, and the data suggest that this formulation will not aggregate after intravenous administration.

3.4. In vitro studies

3.4.1. Adherent monolayer cells

3.4.1.1. Cytotoxicity of free doxorubicin and DHA

The cytotoxicity of free doxorubicin and DHA was investigated in three different human cancer cell lines (Figure 2). The concentration of doxorubicin was fixed at 1 μM (why) while the DHA concentration was varied and the DHA was varied. Maybe introduce ratios between the two drugs? The cytotoxicity in MDA-MB-231 increased parallel to? was a function of the DHA concentration, with an IC50 for DHA by itself where the IC50 for the isolated fatty acid was between 140 and 280 μM . While moderate to now toxicity was detected with 70 μM free DHA (90/5%), co-treatment with 1 μM DOX significantly decreased cell viability (58% vs 69 % free dox alone). It was possible to obtain some cytotoxicity at 70 μM and

the cell viability for isolated doxorubicin and DHA was $69 \pm 2\%$ and $90 \pm 5\%$, respectively, while for the association was $58 \pm 3\%$.

Similarly, in MCF-7 cells ... The second graphic shows the results in MCF-7 and for isolated DHA the IC₅₀ is between 280 and 562 μM . The lowest concentration to obtain some enhancement was 140 μM and with it the cell viability was $97 \pm 7\%$, $55 \pm 3\%$ and $43 \pm 3\%$ for isolated DHA, doxorubicin and associated drugs, respectively. In the resistant cell line MCF-7/Adr (third graphic) the IC₅₀ for the isolated fatty acid was between 140 and 280 μM . It was possible to see some improvement for the association for concentrations as of 280 μM , where the cell viability after incubation with isolated DHA, doxorubicin and associated drugs was $38 \pm 7\%$, $73 \pm 1\%$ and $17 \pm 3\%$, respectively. Thus, the effect of the association seems to be additive and the most sensitive cell line for the association was the MDA-MB-231, which is an accordance with the previous results of the Bougnoux et al. that found a higher susceptibility for this cell line due to the lipid peroxidation caused by DHA (Mahéo et al, 2005; Vibet et al., 2008). Despite this, all cell lines were sensitive to the drug combination at higher concentrations of DHA.

3.4.1.2. Cytotoxicity of the NLC

The cytotoxicity of the NLC was evaluated in monolayer culture for the cell lines MDA-MB-231, MCF-7 and MCF-7/Adr using Cell-Titer Blue (Figure 3). For MDA-MB-231 (Figure 3 A) at 2 μM of doxorubicin (equivalent to 14 μM of DHA when associated) the cell viability for cells incubated with free doxorubicin and free doxorubicin+DHA was $49 \pm 5\%$ and $44 \pm 4\%$, while for NLC and NLC-DHA it was $38 \pm 1\%$ and $32 \pm 2\%$, respectively. The benefit of drug association was apparent from this ratio xx. This is the concentration at which it was possible starting to see some benefits for the NLC-DHA 0.4%. With the highest evaluated concentrations of drugs (16 μM of doxorubicin and 112 μM of DHA), the cell viability was $21 \pm 0\%$, $20 \pm 0\%$, $17 \pm 1\%$, $9 \pm 2\%$ for free doxorubicin, free doxorubicin+DHA, NLC and NLC-DHA, respectively. It is noteworthy that for all of the concentrations from 2 μM of doxorubicin, the formulation with the associated drugs had a more cytotoxic effect compared to the encapsulated non-associated doxorubicin or free drugs.

For the sensitive MCF-7 (Figure 3 B), with 2 μ M of doxorubicin the cell viability was $39 \pm 8\%$, $37 \pm 8\%$, $31 \pm 1\%$, $31 \pm 1\%$ and at 16 μ M it was $18 \pm 1\%$, $17 \pm 2\%$, $14 \pm 0\%$, $12 \pm 0\%$ for free doxorubicin, free doxorubicin+DHA, NLC and NLC-DHA, respectively. Thus, the cytotoxicity for all the evaluated concentrations was very similar for all the treatments.

The cell viability for resistant MCF-7/Adr is described in the Figure 3 C. Higher anticancer activity of NLC-based drug combination over co-treatment with both free drugs was evidenced from 4 μ M dox to 16 μ M dox. At 4 μ M, ..It was possible to see some improvement due to the association and encapsulation from 4 μ M of doxorubicin (28 μ M of DHA) where the cell viability was $62 \pm 8\%$, $63 \pm 2\%$, $37 \pm 2\%$, $30 \pm 1\%$ for free doxorubicin, free doxorubicin+DHA, NLC and NLC-DHA, respectively. The highest cytotoxicity was detected at 16 μ M with xx For the others higher concentrations the activity of the formulations were still better and the best result was found at 16 μ M of doxorubicin (112 μ M of DHA) with $59 \pm 2\%$, $61 \pm 5\%$, $20 \pm 1\%$, $7 \pm 0\%$ of viability for free doxorubicin, free doxorubicin+DHA, NLC and NLC-DHA, respectively. There was no significant difference between free doxorubicin and free doxorubicin+DHA that might be due to the low concentration of the fatty acid. In addition, the Blank NLC did not show any significant cytotoxicity for all the evaluated cell lines.

To confirm these results we have also evaluated the cytotoxicity in monolayer cultures with MCF-7/Adr using the LDH assay (CytoTox 96®) and the results were in agreement with Cell titer blue the same verified by Cell-Titer Blue® (data not shown).

3.4.1.3. Doxorubicin uptake

Doxorubicin uptake was evaluated by FACS? The evaluation of doxorubicin uptake performed by FACS for the three cell lines are described in Figure 4. The drug sensitive cell lines MDA-MB-231 and MCF-7 had the same profile of drug uptake and similar fluorescence intensities for the cells incubated with free doxorubicin, free doxorubicin+DHA, NLC and NLC-DHA. In contrast, for the resistant cell line MCF-7/Adr, we observed a 2.6-fold higher .. the fluorescence of the cells incubated with the formulations were 2.6 folds higher than the cells incubated with the free drugs. There was no difference between free doxorubicin

and free doxorubicin+DHA or NLC and NLC-DHA. Note that no cell-associated fluorescence was detected with the blank formulation. The blank formulation did not result in fluorescent cells.

3.4.2. Spheroids

3.4.2.1. Cytotoxicity

The cytotoxicity of the formulations and free drugs in spheroids was assessed using CytoTox 96® Non-Radioactive Cytotoxicity Assay (Figure 5). The graphic the treatment of the spheroids with NLC-DHA (concentrations) resulted in a $93 \pm 6\%$ LDH release. For NLC, Lipodox, free doxorubicin+DHA and free doxorubicin the release was $51 \pm 13\%$, $44 \pm 5\%$, $35 \pm 10\%$ and $25 \pm 9\%$, respectively. In addition, we visualized through microscope after 24 h of incubation with the treatments formulations a complete destruction of the spheroid, with many scattered loose cells (data not shown) (you can cite someones maybe). It is noteworthy that The blank formulation and the cells treated only with media (control) showed no significant toxicity (less than 2% LDH release and no alteration of the spheroid structure).

3.4.2.2. Doxorubicin penetration

To evaluate the potential of the formulations for penetration of avascular tumors the spheroids, we analyzed the distribution of doxorubicin throughout the tumor spheroids by confocal microscopy (Figure 7). From left to the right, images which represent deeper layers, a reduction of the fluorescence occurred for all the treatments. Differences in the fluorescence intensities between the groups can be organized for all analyzed layers as follows: NLC-DHA 0.4% > NLC 0.4% > Lipodox® > Free doxorubicin+DHA = Free doxorubicin. Furthermore, as example, at 70 μM depth (deepest layer), the spheroids incubated with NLC-DHA 0.4% is notably more fluorescent in the inner core of the sectional cut than the others groups, also showing more penetration for this formulation. The spheroids incubated with the Blank NLC as well as the control group (only media) showed no fluorescence (data not shown). Here you should give numbers, choose the 70 μM

section and check intensity using ImageJ then add this info to the figure and in the text.

3.5. Discussion

Many efforts have been made to improve cancer treatment with combination therapy (Jassem et al, 2001; Storniolo et al, 2008; Livi et al, 2009; Keith et al, 2012), and studies have described the increase of the doxorubicin activity through the association with DHA (Germain et al, 1998; Hardman et al., 2001; Mahéo, 2005; Colas et al, 2006; Bougnoux et al, 2009; Siddiqui et al, 2011; Hajjaji et al, 2012). However, problems related to the route, formulations and schedule **still need** have still to be addressed and nanocarriers have been proposed as a tool to overcome the **se** limitations (Storniolo et al, 2008). Recently, NLC has been described as a promising drug delivery system for enhanced cancer therapy (Zhang et al, 2008; Joshi et al, 2009; Yang et al, 2012). Among the advantages of the NLC is the retention of the drug in the lipid core to promote the control of release. However, works have recommended incorporation of up to 30% of liquid of the total lipid (Radtke et al, 2001; Müller et al, 2002). We hypothesized that a NLC loaded with doxorubicin and DHA triglyceride could enhance the antitumor effect. A NLC was developed by loading doxorubicin and DHA at 0.4% w/v (corresponding to 30% liquid lipid) and evaluated for its release profile in comparison with formulations containing higher DHA concentrations. Our data (Figure 1) clearly showed a controlled doxorubicin release for NLC-DHA 0.4% whereas the NLC-DHA 0.8% (50% liquid lipid) and NE-DHA 1.5% (100% liquid lipid) were unable to retain the drug in the matrices. Despite that, a fast drug release (burst effect) of 30% was verified for NLC-DHA 0.4%. Similar burst effect has been described for SLN and NLC in many works as a characteristic of these formulations (Radtke et al, 2001; Müller et al., 2002). We speculate that this **caveat?** effort may be related to some significant part of the formed ionic pair that is located in the interface of the nanoparticle (as represented in the scheme of Figure 7), and would be quickly released by diffusion after incubation with media. This could be related to the manufacturing process (hot homogenization) that favors the accumulation of the drug in the outer shell of the lipid core (Müller et al., 2002), or **also** due to hydroxyl groups of doxorubicin and carboxyl group of the

oleic acid that confer some amphiphilic character for the ionic pair. Nevertheless, we further speculate that this amount of fast drug release could have a priming effect while the 70% remaining not released up to 48h could have the potential to modify the pharmacokinetics, prolonging the circulation and target the tumor by EPR effect. In addition, to further enrich the targeting issue, it is noteworthy our previous work (Mussi et al, 2013) proposed the ionic pair strategy that resulted in higher release (>80% in the first hour) of the drug in low pH, which might be interesting to tumor site-specific release of doxorubicin. Thus, the formulation NLC-DHA 0.4% which presented interesting physicochemical properties and compatible for intravenous administration was elected for further experiments.

The next step was the *in vitro* evaluation of activity in cell monolayer model with free drugs and the developed formulation in sensitive and resistant breast cancer cell lines. Firstly, we evaluated the cytotoxicity of the free drugs combination and the lowest molar ratio to obtain some improvement was 1:70 of doxorubicin/DHA in MDA-MB-231. (need to introduce ratios before) Secondly, we evaluated the activity of NLC-DHA 0.4% compared with free drugs and NLC (formulation containing only doxorubicin). Although, the ratio of doxorubicin/DHA in the NLC-DHA was 10-fold lower (1:7) than the lowest additive ratio for free drugs? that observed for the improvement of free drugs, the combination showed advantages due to the encapsulation. This was observed in MDA-MB-231 and MCF-7/Adr but not in MCF-7, where higher concentrations of DHA could be necessary. However, the increase of DHA was not possible in this model because concentrations higher than 112 μM would imply using 16 μM dox implies, consequently, the increase of doxorubicin concentration (>16 μM) that would reach 0% of cell viability.

Regarding the results in MCF-7/Adr cells, the advantages of NLC-borne DHA and dox co-delivery were apparent and could be attributed to DHA since uptake of NLC and NLC-DHA were similar benefits of the associated drugs when encapsulated was notably observed and it was due to the activity of DHA, once the doxorubicin uptake verified for both NLC-DHA and NLC were equivalents. Beside this, NLC and NLC-DHA showed meaningly higher activity compared to the free drugs. This system seems to be able to bypass P-glycoprotein efflux pump since

we verified its overexpression in this cell line (data not shown) and **increased dox uptake over free drug** the higher doxorubicin uptake for the formulations was verified/**observed?**. Thus, the encapsulation of doxorubicin is promising to reverse the resistance in cancer cell line monolayer model and the combination with DHA proved to be interesting to further enhance the activity.

The last part of the work was the evaluation of activity in spheroids. They have been described as a more relevant **in vitro** tumor model for use in assessment of drug combinations (Perche and Torchilin, 2012) since they mimic *in vivo* tumors in many ways, including gradients of pH, PO₂ and vascularization (Hirschhaeuser et al, 2010)(**Swati Cancer letters**). Due to these characteristics, this model is more relevant suitable for drug penetration studies *in vitro* in comparison to monolayered cells (Dufau et al, 2012). In addition, spheroids have been used as a tool for negative selection to evaluate drug candidates and most therapeutic approaches were found to be less active in this model than cell monolayer cultures (Hirschhaeuser et al, 2010). The high activity of NLC-DHA 0.4% in MCF-7/Adr was verified for both monolayer and spheroid models, showing cytotoxicity close to 100%. However, the NLC 0.4% was less cytotoxic in spheroids than in monolayer model confirming the expectation aforementioned. **Cytotoxicity in spheroids was confirmed using** These results were also confirmed in spheroids using a different viability assay (CellTiter-Glo® Luminescent Cell Viability Assay; Promega) that evaluates the viable cells based on quantitation of the cellular ATP present (data not shown/**supplemental info?**). The importance of drug encapsulation was clear since the NLC 0.4% was more cytotoxic than free doxorubicin and NLC-DHA 0.4% was more cytotoxic than free doxorubicin + DHA. The combination of doxorubicin and DHA also enhanced the activity verified by the higher cytotoxicity of free doxorubicin + DHA than free doxorubicin and greater cytotoxicity for NLC-DHA 0.4% than NLC 0.4%. Another benefit for NLC-DHA 0.4% was the greater penetration in spheroid structure that overcame the binding **site** barrier where the DHA played some rule. The presence of this barrier, characterized by a limited drug penetration in tumor structure, was confirmed since free doxorubicin was confined to the periphery of the spheroid as previously reported (Perche and Torchilin, 2012 **actually JCR since no confocal in CBT?**)(**Kim biomaterials**) and in

tumor in patients (Lankelma et al., 1999). We also verified an expressively greater penetration and cytotoxicity in spheroids for NLC-DHA 0.4% than a commercial liposomal formulation (Lipodox®). These results strengthen the importance of combination of doxorubicin and DHA as well as their co-encapsulation in NLC.

Altogether, NLC-DHA is a promising formulation with increased anticancer activity over free drugs against three cancer cell lines and in a spheroid model. Taking all together, the NLC-DHA has shown to be promising in terms of the formulation characteristics and its activity that was evidently high in an aggressive cancer cell line MDA-MB-231 and the drug resistant MCF-7/Adr compared to the two commercially available forms of doxorubicin (free hydrochloride salt and liposomal). Thus, we propose this newly developed nanocarrier codelivering doxorubicin and DHA to have the potential for effective combination cancer therapy. that have a potential for treatment of drug sensitive and resistant cell lines to qualify as a truly multidrug delivery nanomedicine for cancer therapy.

3.6. Conclusion

Our newly developed nanostructured lipid carrier (NLC) loaded with doxorubicin and DHA shown size, zeta potential and serum stability adequate for parental administration and a controlled release. The in vitro antitumor activity of such NLC loaded with doxorubicin and DHA 0.4% in monolayer models was the same as the free drugs for the sensitive MCF-7, slightly higher for MDA-MB-231 and significant for MCF-7/Adr compared to the free drugs and the entrapped drug not associated with DHA. Thus, the association of doxorubicin and DHA as well as their co-encapsulation in NLC improved the antitumor activity in these aggressive tumor types and may overcome drug resistance associated with P-glycoprotein activity. These findings with cell monolayer were supported spheroids that showed an enhanced penetration into the tumor structure. Finally, the NLC loaded with doxorubicin and DHA represents a promising alternative combination cancer therapy.
