KEYWORDS:

Antibacterial P/F-modified TiO₂ coating, photocatalytic activity, immediate versus long-term biofilm-preventive activity, mechanism, surface topographic properties.

ABSTRACT

Photocatalytic antibacterial and biofilm-preventive activity in liquid of heavy-metal-free coatings based on a phosphorus (P) and fluorine (F) -modified TiO₂ photocatalyst has been investigated. They reveal significantly higher immediate and longer-term (biofilm-preventive) inactivation capacity than a reference coating made of the commercial photocatalyst TiO₂ P25 on three bacterial species differing in cell wall type and ability to resist oxidative stress (*Escherichia coli*, *Staphylococcus epidermidis*, *Pseudomonas fluorescens*) (up to more than 99% reduction of colonization on P/F-modified TiO₂ coating compared to about 50% on P25 TiO₂ coating for 10 min UV-A illumination). This results from the P- and F-induced improvement of photocatalyst properties and from the smoother surface topography, which shortens reactive oxygen species (ROSs) diffusion to the outer membrane of the targeted adhered bacteria. Decrease in ROSs-related impairment of cell wall, respiratory and enzymatic activities confirms the loss of ROSs throughout the bacterial cell degradation. *Staphylococcus epidermidis* and *Pseudomonas fluorescens* are less sensitive than *Escherichia coli*, with a probable relation to the bacterial oxygen stress defense mechanism. The coating antibacterial efficacy was highly affected by phosphate ions and the richness in dissolved oxygen of the reaction medium.

1. Introduction

Surface adhesion of bacteria and formation of biofilm ¹ present health threat in many instances such as biomedical field, ² food industry, ³ water distribution ⁴ and wastewater treatment. ⁵ Apart from conventional physico-chemical surface treatments, an alternative method for reducing frequency and level of surface contamination has been proposed in the last two decades: the self-disinfecting surfaces. ⁶⁻⁸ Nowadays, surfaces impregnated, functionalized or coated with silver or copper are the most advanced. ⁹ However, the development of surfaces with active biocidal agent but harmless doses for human health is delicate. ¹⁰ As a consequence of the surface redox properties developed by the TiO₂ semiconductor under ultraviolet A irradiation (UVA, 320–400 nm), TiO₂ mostly in its anatase form exhibits strong antibacterial effect owing to the generation of various reactive oxygen species (ROSs) from photogenerated charges. ¹¹ Applying TiO₂-incorporated surfaces for self-disinfection enabled bacterial inactivation, even up to complete mineralization ¹²⁻¹³ on a wide range of Gram-negative and Gram-positive bacteria species.

Aside from irradiation source power, ¹⁴ treatment time ¹⁵ and matrix (or substrate)-related factors, ¹⁶⁻¹⁷ the intrinsic physico-chemical properties of TiO₂ greatly affect the photocatalytic oxidation performance of the coating by influencing the amount, recombination rate and diffusion length of the photogenerated charges. ¹⁸ The role of TiO₂ itself was addressed in many studies by comparing the bactericidal performance of new TiO₂ coatings ¹⁹ to that made of P25 TiO₂, ²⁰ the commercial photocatalyst largely admitted as a reference. The self-disinfection properties were improved thanks to chemical modifications of TiO₂, mainly involving Ag and Cu. However, Ag/Cu-modified TiO₂ is expected to reveal high bactericidal properties directly due to the heavy metals. ²¹ Other studies focused on the building of TiO₂-based heterojunctions ²² or TiO₂ doping, ²³ to provide self-

disinfection properties under visible light. Meanwhile, TiO₂ coatings with extended bactericidal efficiency under UVA irradiation without releasing of environmental-unfriendly agents such as heavy metals are lacking.

Efficacy of TiO₂-based self-disinfection coatings also depends on the surface-related properties, especially those resulting from the weight of TiO₂ deposited per surface area as well as from the surface morphology and texture, closely related to the size of the particles or of their aggregates. They directly impact the photocatalytic activity¹⁶ and also change the surface area of contact between TiO₂ and the adhered bacteria, thus affecting the degree of ROSs attack on cells. Further, both chemical and topographical surface properties, which change with the photocatalyst density and chemistry, modulate the amount of adhered and hence targeted bacteria.²⁴ If present, the matrix in which the particles are embedded also modulates the disinfection efficiency by influencing bacterial adhesion²⁵⁻²⁶ and may create a synergetic effect with the photocatalyst.¹⁸ Other factors like the presence of ions and the oxygen content in the liquid environment may also influence the photocatalytic activity, thus having dramatic consequences for the performance in real aqueous phase conditions.²⁷ However, except regarding the matrix, these topics are usually omitted.

Besides, bacterial inactivation on TiO₂-based coatings is usually addressed by counting viable or cell wall-damaged cells.¹¹ Rare studies also investigate the photocatalytic toxicity to intracellular functions such as enzymatic and respiratory activities.²⁸⁻²⁹ However, they only touch upon TiO₂ nanoparticles or nanocomposites but fail for TiO₂ coatings. Hence, actual impairment of vital intracellular functions in bacteria adhered and treated thanks to TiO₂ coatings has still to be clarified. Besides, bacteria are able to overcome the photocatalytic treatment thanks to ROSs defense mechanisms involving catalase and superoxide dismutase (SOD).³⁰⁻³¹ In the case of

oxidative damages caused by TiO₂, the immediate inactivation rate of bacteria was shown to be inversely proportional to SOD and catalase activities.³² In addition, a SOD- and catalase-deficient mutant strain was reported to be much more sensitive to photocatalytic treatment than the wild strain.³³ Importantly, this capacity varies with species and strains³⁰ and can enable bacterial repair during the post-irradiation period.³⁴ Accordingly, the high immediate antibacterial efficacy of a self-disinfection coating cannot ensure high post-photocatalytic longer-term performance. To our knowledge, this has been never investigated for immobilized TiO₂ especially regarding variations according to bacterial species and their sensitivity to oxidative stress.

We report here the photocatalytic liquid-phase antibacterial activity of a novel phosphorus (P) and fluorine (F) -modified TiO₂ photocatalyst immobilized as a coating, which is expected to provide higher bactericidal efficiency under UVA light than a reference coating made of TiO₂ P25 catalyst without releasing any environmental-unfriendly agent. The P/F-modified TiO₂ powder was developed in a previous work and revealed higher activity in the photocatalytic degradation of gaseous methylethylketone compared to TiO₂ P25.³⁵ Here, both immediate curative performance and the corresponding longer-term biofilm-preventive antibacterial efficacy of the TiO₂ coatings were analyzed, for the first time, by *in situ* monitoring growth of bacteria adhered on such coatings. Impact of the photocatalytic treatment on the cell wall and on the vital respiratory and enzymatic functions was also *in situ* studied by following cell wall permeability as well as redox and esterase activities. Potential effect of the cell wall type and ability to resist oxidative stress of bacteria was questioned by using three bacterial species (*E. coli*, *Staphylococcus epidermidis* (*S. epidermidis*) and *Pseudomonas fluorescens* (*P. fluorescens*)) differing in these terms. Possible correlations between physical surface characteristics of the coating and chemical intrinsic properties of the

TiO₂ photocatalyst on one side, and the antibacterial efficacy on the other side were considered. Effects of certain ions and richness in dissolved oxygen of the reaction medium were also explored.

2. Experimental

2.1. Sample preparation

Aeroxide® P25 TiO₂ photocatalyst was purchased from Evonik® (Evonik Resource Efficiency GmbH, Hanau-Wolfgang, Germany) and is referred to as “P25”.

The synthesis of the novel P/F-modified TiO₂ photocatalyst was described elsewhere.³⁵ Briefly, 5 g of titanium (IV) isopropoxide (Ti(OⁱPr)₄, 97%, Aldrich) was mixed in 10 g of propan-2-ol (AnalaR Normapur, >99.5%, VWR Chemicals), before 6.2 g of 2.2 mol/L acetic acid solution containing 21.7 mg of sodium fluoride (NaF, ACS reagent, ≥99%, Sigma-Aldrich) and 59 mg of phosphoric acid (H₃PO₄ (PA), analytical reagent, ≥85%, R.P.Normapur) was further added dropwise. NaF and PA additives provided the fluoride anions (F⁻) and the phosphate anions to the synthesis medium, respectively, with a F/Ti and P/Ti molar ratio of 0.03. A white milky precipitate was formed immediately, and the solution was kept under stirring for 1 h before being further sealed by parafilm and aged at room temperature for 6 days without any stirring to partially generate anatase nanoparticles by crystallization. After filtration of the powder from the rest of the solvent, the solid was dispersed in 50 mL distilled water under stirring for 10 min, before being separated from liquid by centrifuge. The washing-centrifuge cycle was repeated 2 times. After drying for 2 h at 100 °C, the so-obtained white powder was finally calcined in air at 550°C for 2 h with a heating rate of 5°C/min in attempt to increase crystallinity and to remove fluorine adsorbed on the sample surface.³⁶ This sample is referred to as “PANaF”.

For the preparation of coatings, 484 mg of both TiO₂ photocatalysts were separately dispersed in 1 ml of 96% ethanol (0.484 g/ml) followed by 5 min of ultrasonication in a 100 W ultrasonic cleaner. Then the TiO₂ suspensions were evenly deposited on borosilicate glass cover slips (ROTH Karlsruhe Deckglaser 22 x 22 mm) by drop casting with a surface density of 1 mg/cm², while the substrates were continuously dried from below with a hairdryer. Drying was completed in several minutes. Both TiO₂ immobilized samples are referred to as “TiO₂ coatings”.

2.2. Characterization of photocatalysts

X-ray diffraction (XRD) patterns of TiO₂ powders were recorded on a D8 Advance Bruker powder diffractometer in a θ/θ mode and using the K α_1 radiation of Cu at 1.5406 Å. Surface area of TiO₂ powders were measured on an ASAP2010 Micromeritics Tristar 3000 analyzer using N₂ as an adsorbent at 77K. Before N₂ adsorption, samples were outgassed at 150°C for 12 h. BET surface area was calculated from the N₂ adsorption isotherm.

Transmission Electron Microscopy (TEM) analysis of TiO₂ powders was performed using a Philips CM200 in standard mode observation, equipped with thermo-ionic LaB₆ filament, operating at a 200 kV acceleration voltage. Samples were firstly grinded and sonicated in ethanol solution, before a drop of the solution was deposited onto a copper grid covered by holey carbon membrane for observation.

Surface topographical properties of TiO₂ coatings were analyzed by AFM by using a NanoScope IIIa with the following parameter settings: Tapping mode; Tip thickness of 7 μ l, length of 225 μ m, width of 38 μ m; Resonance frequency of 190 KHz; Force constant of 13-77 N/m; Image size of

1 μm $\times$ 1 μm for 5 different zones on each sample. Surface roughness was extracted from each micrograph after adequate image treatment and analysis by WSxM 9.1 (www.wsxm.es).

X-ray Photoelectron Spectroscopy (XPS) surface characterization was performed on an XPS spectrometer SES-2002 (VG SCIENTA) apparatus equipped with an Al K α (1448.6 eV) source with a pass energy of 20 eV. The spectra were decomposed assuming contributions with Doniac-Sunjic shape³⁷ and Shirley background subtraction.³⁸

2.3. Bacteria strains and culture methods

–80°C frozen bacterial cells were spread on LB (Lysogeny broth, Sigma-Aldrich) agar plate and cultured for two nights at 30°C for *E. coli* SCC1,³⁹ or 37°C for *S. epidermidis* ATCC 35983 (CIP 106510), or on BHI (Brain-Heart-Infusion, Sigma-Aldrich) agar plate at 30°C for *P. fluorescens* ATCC 13525 (CIP 69.13T). Then, precultures were prepared with one colony of *E. coli* or *S. epidermidis* in LB, or of *P. fluorescens* in BHI, before overnight incubation at 30°C, 37°C and 30°C, respectively. Cultures were prepared with 10% volume of the precultures in fresh LB for *E. coli* and *S. epidermidis*, and with 33.3% volume of the preculture in fresh BHI for *P. fluorescens*. Cultures were then incubated for 4 h at 30°C or 37°C before bacteria were harvested by centrifugation. Harvested bacteria pellets were re-suspended either in physiological NaCl (9 g/L, pH 6.8) solution or in the so-called M63G, a *E. coli*-selective minimum medium (pH 6.8).⁴⁰ The obtained bacterial suspensions were adjusted to an absorbance at 600 nm ($A_{600\text{ nm}}$) of 0.1 (5×10^7 CFU mL⁻¹) for being ready to inoculate the TiO₂ coatings. As a reference, i.e. internal control of bacterial adhesion and sessile population growth, cleaned borosilicate glass cover slip surface was inoculated and further analyzed similarly to the TiO₂ coatings.

2.4. Photocatalytic antibacterial activity of TiO₂ coatings

2.4.1. Immediate antibacterial effect

Coatings were sterilized by UVC irradiation ($\lambda=245$ nm) for 7 min at a 2 cm distance before immersion in 3 ml of freshly-prepared M63G medium (exclusively for *E. coli*) or physiological NaCl (9 g/L) medium (for all three species) in Petri dishes (ROTH, standard petri dish, PS, 35 mm diameter, 10 mm height). After 3 h of incubation at 30°C or 37°C, the coatings were washed three times by 2 ml physiological NaCl without creating air-surface interface and ended being immersed in the last washing solution. Two of the three identical coatings of each type were exposed for 10 min or 45 min (and 3 h if necessary *i.e.* only for *P. fluorescens*) to UVA irradiation. The third coating was maintained without irradiation as a non-illuminated reference. The UVA irradiation was provided by using a 8W UV-A blacklight lamp (Sylvania Blacklight Blue F8W/BLB T5) located at a 1.5 cm distance above the coating samples (light distribution centered on $\lambda=365$ nm with a received irradiance of 30 W/m² recorded using a RPS900-W ILT wideband spectroradiometer). For each illumination duration on control, P25 and PANaF coatings, experiments were repeated three times using three identical coating duplicates of each coating type. A last washing was performed after photocatalytic treatment to remove any planktonic bacteria. And in this last washing solution, Fluorescent Syto9® (Aldrich-Sigma) and propidium iodide (PI, Aldrich-Sigma) dyes were added (no Syto9® stain for *E. coli* SCC1) to stain viable or membrane-damaged bacteria respectively.

Observations of coating's colonization by bacteria were then conducted under confocal microscope (LSM700, Carl ZEISS) equipped with a X63 water immersion objective (W Plan

Apochromat X63/1.0, 2.0 mm) and working in fluorescence mode with the excitation laser at 488 nm and with acquisition wavelength at 528 nm and 645 nm for Syto9® (GFP for *E. coli* SCC1) and PI emission, respectively. Bacteria with active green GFP metabolism (for *E. coli*) or stained in green by Syto9® (for *S. epidermidis* and *P. fluorescens*) are called “Live” in the following text, while those with damaged membrane as demonstrated by the red staining of PI (for all bacteria species), are called “Damaged” in the following text. The obtained double-channel images in RGB form were analyzed via ImageJ 1.47V® software to access quantity of stained bacteria in terms of surface coverage fraction. Three different locations of each surface sample were observed, located on the diagonal line (Figure S1).

2.4.2. Longer-term biofilm-preventive antibacterial effect

The longer-term antibacterial efficiencies of the coatings, *i.e.* post photocatalytic action, were determined for different UVA illumination durations. The general procedure is similar to that conducted for immediate antibacterial effect analysis, except that the coatings were put back into an adequate nutritive culture medium immediately after UVA illumination. They were kept overnight at 30°C or 37°C for *E. coli* or *P. fluorescens*, and *S. epidermidis* respectively, before being washed and stained for the final confocal microscopy observation. For the *P. fluorescens* strain, a 3 h UVA illumination experiment was also performed.

2.4.3. Photocatalytic action mechanism

The experimental procedure was similar to that used for the analysis of immediate antibacterial photocatalytic effect but conducted on *E. coli* PHL 628, a biofilm-making K12 MG1655 derivative strain⁴¹ without fluorescence properties like that of *E. coli* SCC1. After UVA illumination, Calcein AM (CAM, Aldrich-Sigma) and 5-cyano-2,3-ditolyl tetrazolium chloride (CTC, Aldrich-Sigma) fluorescent dyes were simultaneously used to stain bacteria with intact endogenous intracellular

esterase activities and redox respiratory activities respectively. Staining was performed in LB medium to reach a detectable level of bacterial respiratory activity.⁴² On each surface sample, NaCl 9 g/L solution was thus replaced by 2 ml of solutions of CAM (3 mmol/L) and CTC (1 mmol/L) dyes in LB before 20 min incubation. Surface samples were then washed once by physiological NaCl 9 g/L medium without creating air-surface interface and finally observed under confocal microscope as described above. Excitation laser was at 488 nm and the emission was observed at 520 nm for CAM and 630 nm for CTC.

2.4.4. Photocatalytic bactericidal action in oxygen-deficient condition

Immediate antibacterial effect of photocatalysis in oxygen-deficient condition has been evaluated on the *E. coli* SCC1 strain cultured in a confined environment (Figure S2). Briefly, 20 μ l of bacterial suspension prepared with freshly-autoclaved medium (therefore with oxygen deficiency) was dropped on each coating, which was immediately covered by a glass cover slip. The air-liquid exchange interface area was thus limited at the outer edge of the double glass cover layer. Then UVA illumination was performed as described above and prolonged up to 3 h since the photocatalytic activity was expected to drastically decrease in confined environment. In addition to the confocal microscopy analysis performed as described above, quantity of sessile bacteria was also assessed by using a classical plate counting method.⁴³ Glass cover slip was confirmed not to absorb neither UVA nor the fluorescence emitted by bacteria or bacterial staining.

Besides, the variation of the oxygen content during the photocatalysis action in confined environment was monitored by using an oxygen sensor patch (HIOXY Oxygen Sensor patch, IDIL). In the above described confined environment setup, the patch was stuck on the interior side of the top cover slip, sandwiching liquid along with the TiO₂ coating (Figure S3). The liquid used in this experiment was either distilled water, fresh bacteria-free physiological NaCl 9 g/L medium

or bacteria suspension adjusted to an absorbance $A_{600\text{ nm}}$ of 0.1 or 1.0. Oxygen dissolved in liquid quenches the fluorescence of the sensor, allowing a modulation of the fluorescence intensity level vs. the dissolved oxygen concentration by observation under an up-right epifluorescence microscope (Olympus BX51). Excitation laser was at 405 nm and emission was observed at 630 nm. UVA illumination was applied on the bottom side of the coatings with the same irradiance as before. To compare the oxygen content with and without UVA illumination, micrographs were taken with both non-illuminated and illuminated coatings.

2.4.5. Data statistics

Significance of the two-by-two differences between averages of bacteria's quantity on the diverse coatings was evaluated by bilateral Student's t tests with significance thresholds of 0.05. According to Scherrer,⁴⁴ the alternative hypothesis ($H_1: \mu_{P25} \neq \mu_{PANAf}$) was assumed to be true when the main hypothesis ($H_0: \mu_{P25} = \mu_{PANAf}$) was rejected.

3. Results and discussion

3.1. Immediate photocatalytic antibacterial effect on *E. coli* SCC1

Surface fraction covered by *E. coli* SCC1 before and after illumination on the reference surface, P/F-modified and P25 TiO_2 coatings are shown in Figure 1 and Figure S4. Colonization was similar before illumination on all the three types of surface (TiO_2 coatings and reference), which indicates that the TiO_2 coatings do not present any noticeable attractive or repellent properties for bacteria compared to the reference. After surface inoculation and subsequent bacterial adhesion, no significant bacterial growth was observed neither on the reference surface nor on the TiO_2 coatings, as expected in NaCl 9 g/L medium. Regarding immediate photocatalytic effect, a 10 min

UVA treatment resulted in a strong reduction of bacterial activity on P/F-modified TiO₂ (“PANaF”) coating, with almost complete elimination of the sessile “Live” population. In contrast, a 10 min UVA treatment on P25 coating only provided about 50% of “Live” population decrease, with high variability of the results with samples and locations on samples. This is illustrated by the confocal micrographs in Figure S5 B, C, which display very different ratios of “Live” to “Damaged” bacteria numbers depending on the analyzed region on P25 coatings. After 45 min of UVA illumination however, a similar strong reduction of the quantity of “Live” bacteria was observed on PANaF and P25 coatings. Besides, the quantity of “Damaged” bacteria increased with the irradiation time up to the colonization level by “Live” bacteria measured before illumination. The average “Damaged” gain-to-“Live” loss ratios for 10 min and 45 min illumination are 1.71 and 0.84 on P25 coatings, and 1.09 and 1.15 on PANaF coating respectively. In general, good correlation was found between loss in “Live” bacteria and gain in “Damaged” bacteria for all the coatings and all illumination time. This clearly indicates that bacteria were not eradicated; rather their cell wall was more or less strongly degraded according to coating type and illumination time.

Immediately after 10 min of UVA illumination, enzymatic and respiratory activities of bacteria on TiO₂ coatings were not affected (Figure 2, Figure S6, Figure S7 and Figure S8), as shown by the absence of any significant difference in the quantities of CAM- or CTC-positive bacteria respectively. In contrast, 45 min illumination resulted in a strong reduction in the quantity of CTC-positive bacteria on both coating types, which was more significant on the PANaF coating. Reduction in respiratory activity is in accordance with the increase in physical damage of the cell wall, as shown by PI staining. A 45 min photocatalytic treatment also resulted in a loss in the quantity of CAM-positive bacteria, which was also more marked on PANaF coating than on P25 coating. This is indicative that bacteria have been hit at a sufficient level to inhibit any enzymatic

activity in a large part of the bacterial population (80% and 60% on PANaF and P25 coatings, respectively), even though cells were not completely degraded.

3.2. Relation between the physico-chemical properties of the coating and the antibacterial activity on *E. coli* SCC1

PANaF TiO₂ coatings present higher photocatalytic activity than the P25 reference coating in terms of immediate cell wall damage and reduction in vital metabolic activities of *E. coli* cell. Experiments conducted without illumination or without TiO₂ coatings demonstrated that neither UVA illumination nor TiO₂ coatings were able by them-selves to induce these antibacterial effects. Absence of toxicity of TiO₂ coatings was made sure by the preservation of very high “Live” and very low “Damaged” bacteria’s quantity on TiO₂ coating samples in the absence of illumination (Figure S4, Figure S9). In addition, neither 10 min (data not shown) nor 45 min of UVA illumination (Figure S9) resulted in any loss of “Live” bacteria and any gain of “Damaged” ones on reference surfaces. The applied irradiance was thus unable to induce any detectable damage of bacterial cells. 3 h of UVA illumination had to be reached to achieve a slight killing effect on *E. coli* SCC1, with non-significant variation of the “Live” bacteria population but high increase in the “Damaged” population (Figure S10). In addition, the electrostatic interactions between the charged bacterial outer surface (negative for all known bacterial species at physiological pH, about 7) and the material surface, which are known to impact bacterial adhesion,¹ are expected to have been similar on TiO₂ P25 and PANaF materials.⁴⁵ Both materials exhibit isoelectric point (IEP) of 5.6 ± 0.5 and 3.4 ± 0.2 , respectively, ie. lower than the physiological pH, so that both surfaces are negatively charged in the most common bacterial culture media (pH = 6.8-7.0).⁴⁶ This was confirmed by the experiment that showed that sessile *E. coli* bacteria were in similar amount on

P25 and PANaF coatings before any photocatalytic treatment. Damage and inactivation of bacteria observed with up to 45 min of treatment should be thus attributed to photocatalysis, i.e. the physico-chemical properties of the TiO₂ photocatalysts or of the coatings.

PANaF TiO₂ is expected to perform better than the P25 TiO₂ reference for many different aspects. XRD patterns revealed that the PANaF TiO₂ powders had a smaller mean crystallite size than the P25 TiO₂ reference (about 10-11 nm vs. 22 nm for the anatase phase in P25) (Figure 3), associated to its higher specific surface area (130 m²/g vs. 55 m²/g). The results were confirmed by TEM analysis, for PANaF and P25 TiO₂ powders (with a 12-15 nm mean crystallite size vs. 22-25 nm, respectively). It was shown that this fine-tuned material morphology directly results from the use of phosphoric acid (PA) and sodium fluoride (NaF) additives in a P/F-assisted sol-gel synthesis of TiO₂. Thanks to the use of both additives, a much higher photocatalytic activity in the gas-phase methyl ethyl ketone degradation was obtained with PANaF TiO₂ in comparison to P25. Indeed, the number of adsorption and reaction surface sites was increased and an improvement of the photogenerated electron-hole charge flow separation was proposed, which reduces the charge recombination rate.³⁵ Here as well, the increased number of surface sites favors the production of ROS, and consequently the subsequent antibacterial effect in aqueous phase.

Besides, the surface topographic properties are likely to provide some advantage to the PANaF coating over its P25 counterpart. As measured by AFM and reported in Figure 4, strong differences in surface roughness and morphology are noticed: the surface of the P25 coating is composed of large grain-like convex structures with size of 180 ± 35 nm, while the PANaF coating surface is smoother (mean lateral particle size of 75 nm vs. 120 nm for PANaF and P25, respectively) and the grain size is smaller (42 ± 16 nm). This is consistent with the smaller TiO₂ crystal size of PANaF compared to P25. Indeed, even though the observed grains are probably aggregates rather

than single crystals, smaller crystals are expected to form smaller aggregates than larger crystals do, if the form of primary particles is non-anisotropic. This has been especially shown for aggregates of P25 and of smaller size sol-gel TiO₂.⁴⁷ This difference in topography does not result in different surface coverage by bacteria of the coatings as shown before UV-A illumination (Figure S4). However, the photocatalytic effect on adhered bacteria might be impacted. Due to their large size (1-3 μm) compared to the TiO₂ aggregates, bacterial cells lie on the coating's surface with only a limited numbers of contact points.⁴⁸ On PANaF coatings, the smoother topography results in a higher number of contact points with shallower valleys in between. This is beneficial to the photocatalytic activity,⁴⁹ since the reactive generated ROSs need to diffuse for a shorter distance to reach the target i.e. the bacterium at the surface of the PANaF coating compared to the P25 coating (Figure 4), which has been reported to prevent dramatic loss of the ROSs.⁵⁰

Longer-term, biofilm-preventive antibacterial effect

Bacteria's fate on the coatings after treatment by photocatalysis has been investigated. Adhered *E. coli* were allowed to recover for 16 h in favorable growth conditions after different photocatalytic treatment times. Their amounts after the recovery period are depicted in Figure 5 and Figure S11, and some typical micrographs are shown in Figure S12. As expected, the surface coverage by “Live” bacteria without photocatalytic treatment increased from 15-20 % to up to 40-50 % on the TiO₂ coatings after overnight culture in nutrition-rich conditions. In contrast, the surface coverage increased from nearly 0% when a prior UV-A treatment was applied for 10 min or 45 min to 15-20 % on both P25 and PANaF coatings after overnight culture. Overall, the longer-term antibacterial effect of the TiO₂ coating is able to limit the bacterial overnight regrowth to roughly 60% of surface coverage relative to that on a non-treated coating (Figure 5 B). This demonstrates that the few “Live” bacterial cells still adhered on the coatings after photocatalytic treatment

(Figure 1C) were able to grow if placed in favorable conditions. However, only few bacteria that were damaged by the treatment were able to recover, as suggested by the similar fraction of bacteria remaining “Damaged” (i.e. red) after the overnight culture (10%) (Figure 5 A) compared to the fraction measured directly after the photocatalytic treatment (10-20%) (Figure 1 C).

3.3. Variations of the photocatalytic antibacterial performance with bacterial species

The photocatalytic antibacterial performance, regarding both immediate and longer-term effects, was expected not to depend only on the material and the coating properties, but also on the bacterial species mainly due to strong differences in resistance to oxidative stress. Investigation conducted with *S. epidermidis* ATCC 35983 (CIP 106510) and *P. fluorescens* ATCC 13525 (CIP 69.13T) strains on the PANaF and P25 coatings revealed significant differences in the photocatalytic effect compared to the results observed with *E. coli*.

With *S. epidermidis* ATCC 35983 (CIP 106510), the results reveal a strong reduction of the “Live” bacteria quantity on both the coatings after 45 min UVA illumination (Figure 6 A, Figure S13 and Figure S14 for micrograph examples). However, 10 min UVA treatment failed to cause any antibacterial effect on P25 coating and only a slight advantage of PANaF coating was evidenced with “Live” bacteria quantity being reduced to about 80% of the initial population. 10 min UVA treatment also failed to provide any antibacterial effect on *P. fluorescens* ATCC 13525 (CIP 69.13T) strain on the P25 coating, but also on the PANaF coating (Figure 6 B and Figure S15). Nevertheless, 45 min UVA illumination led to a significant reduction of the “Live” bacteria quantity on both P25 and PANaF coatings, but the reduction was only of about 70% on the PANaF coating and 50% on the P25 coating, thus not as efficient as with *E. coli*. In addition, as illustrated

in confocal micrographs (Figure S16), some bacterial cells were stained as dark orange instead of red, which is the result from double cell staining by red PI and green Syto9®. This indicates that the cell wall integrity was affected, even though damages were not strong enough to allow PI to completely replace Syto9® in DNA. Longer UVA treatment, tested for up to 3 h illumination, did not result in any further improvement of the antibacterial effect as seen in Figure 6 B.

After overnight growth in nutrient-rich culture medium without any previous treatment, *S. epidermidis* population that initially covered about 10% surface of the coatings grew to about 50% coverage in absence of photocatalytic treatment (comparison between Figure S15 and Figure S17). With a previous 10 min UVA treatment, the bacterial population was unchanged (49% and 50% on P25 and PANaF coatings respectively) (Figure 6 C, Figure S17 and Figure S18). However, with 45 min UVA illumination, longer-term growth was significantly reduced, the coverage by “Live” bacteria being lowered to 40% of the P25 coating and about 30% of the PANaF coating. “Damaged” bacteria quantity was almost unchanged after the overnight growth in favorable conditions compared to immediately after the photocatalytic treatment, which suggests that damaged bacteria were mainly unable to recover, similarly to that observed with the *E. coli* SCC1 strain. Thus, photocatalytic treatment of *S. epidermidis* on both P25 and PANaF TiO₂ coatings was able to inhibit the growth of a significant part of the sessile bacterial population even after a long recovery time in favorable conditions. In contrast, 45 min of treatment failed to avoid the formation of a thick *P. fluorescens* biofilm after post-treatment growth in nutritive medium (Figure S19) even though the micrographs suggest some moderate inhibition on both TiO₂ coatings (Figure S20). A more pronounced inhibition was achieved after 3 h illumination as evidenced by the much less dense “Live” bacterial biomass observed in the biofilm. In addition, “damaged” bacteria were in higher quantity on the PANaF coating than on the P25 one.

Finally, bacterial species are ranked as following in terms of their rate of inactivation after the same photocatalytic treatment on the same TiO₂ coating: *E. coli* > *S. epidermidis* > *P. fluorescens*, from the most to the least sensitive. Indeed, the possible effect of differences in adhesion rate between species is rejected since the inactivation rate relates to the number of adhered bacteria of each species measured without treatment. Therefore, three species-related factors may be involved in this variation in sensitivity: 1) the production of extracellular matrix (ECM), 2) the structure properties of the bacteria cell wall and 3) the defense mechanism countering ROSs.

ECM is expected to form a screen that partially hides the TiO₂ nanocrystals from the irradiation beam.⁵¹ It also probably acts as a diffusion barrier for ROSs that have been produced.⁵² However, illumination treatments were all carried out on bacteria just adhered (3 h of incubation) in physiologic saline solution, which is not expected to conduct to the formation of a significant biofilm.⁵³ Hence, ECM is here expected not to have been produced in a sufficient quantity to compromise the photocatalysis effect.

Bacteria's cell wall type might also vary the bacterial susceptibility to ROSs. Indeed, both outer membrane and peptidoglycan (PGN) layers, which are the main barriers for ROSs before damaging the cytoplasmic membrane, differ with Gram-negative / Gram-positive class of bacteria (Figure 7).⁵⁴ Lipopolysaccharide and lipid layers of the outer membrane of Gram-negative bacteria have been demonstrated to be easily degraded through photocatalysis.⁵⁵⁻⁵⁶ In contrast, the PGN layer, that is much thicker in Gram-positive bacteria, was shown to be the most resistant component of the cell wall.⁵⁷ However, the natural pores of the PGN layer are large enough for the diffusion (bypass) of ROSs (if live long enough) in the absence of any PGN degradation.⁵⁴ Therefore, variation of sensitivity based on the typical cell wall composition associated to the Gram-positive and versus Gram-negative classification is not obvious. This is in agreement with

the literature that failed to report direct correlation between photocatalytic antibacterial efficacy and the cell wall type so far.⁵⁸

Whatever the cell wall type, ROSs finally reach the cytoplasmic membrane. There, vital metabolic functions such as enzymatic and respiratory activities may be affected.^{42, 59} This is therefore the ultimate and the most vital defensive line against many environmental stresses⁶⁰. In our study, adhered *E. coli* cells with active enzymatic and respiratory activities were still in high number on both TiO₂ coatings after 45 min of UVA treatment, although their GFP production, which signs the metabolic activity, was shown to be almost completely inactivated. Their cell wall was also almost completely damaged. In addition, the enzymatic activity was less reduced than the respiratory activity. This confirms that ROSs attacked the cytoplasmic membrane as first, which is the location of *E. coli* respiratory, while the remaining quantity of ROSs reached then the cytoplasm (Figure 7). In the bacterial cell cytoplasm, all three bacteria used in the present work had catalase and SOD, two important anti-oxidative enzymes providing defenses against ROSs. However, their capacity to inhibit ROSs varies with species.⁶¹ Facultative anaerobic *S. epidermidis* and *E. coli* bacteria are more sensitive to oxygen exposure than aerobic organisms that have moved towards intricate mechanisms to neutralize ROSs.⁶²⁻⁶⁴ Thus, Alhasawi *et al.* have demonstrated that an obligate aerobic wild *P. fluorescens* strain can survive in media with 500 μ M H₂O₂ by generating NADPH, ATP and glyoxylate in an effort to fend off ROSs.³¹ This pronounced difference in fighting against ROSs is the probable main cause of the difference in sensitivity to the photocatalytic treatment observed between *E. coli* and *S. epidermidis* on the one side and *P. fluorescens* on the other side. In addition, *E. coli* K12 strains such as *E. coli* SCC1 lack one of the SODs compared to environmental *E. coli* B strain. This allows us to suggest that *E. coli* SCC1

bacteria exhibit less resistance to ROSs in comparison to *S. epidermidis* and *P. fluorescens* bacteria, *P. fluorescens* being the most resistant due to adequate adaptation to aerobic conditions.

3.4. Influence of oxygen and ions on the photocatalytic antibacterial performance

Environmental factors such as the oxygen level and the presence of ions in the reaction medium are prone to strongly affect the photocatalytic antibacterial effects. We therefore investigated the immediate photocatalytic antibacterial effect in a confined, *i.e.* O₂-poor, environment (Figure 8) for *E. coli* SCC1 strain on both P25 and PANaF coatings. The surface fraction covered by bacteria without treatment was low (2%-5%) in agreement with the low bacteria's quantity inoculated on the surface in the confined environment (only 20 µl of bacteria suspension). After a 45 min UVA treatment, neither P25 nor PANaF coating revealed any significant reduction in the quantity of “Live” bacteria, which is in a great contrast with the results obtained in the “open” aerated system used for the above reported results (Figure 1 B). The lack of significant photocatalytic activity on the confined TiO₂ coatings was confirmed after 3 h UVA illumination (data not shown). Noticeably, the lack of antibacterial effect was associated with a color change of the TiO₂ coatings (Figure S21). Typically, the coating revealed white color in aerated conditions, which was unchanged after illumination. Placed in the confined environment, the coating turned from white to a bluish color, regardless of the concentration of bacteria used for the inoculation, which is attributed to the formation of reduced TiO₂ (Ti³⁺) with the formation of oxygen vacancies.⁶⁵⁻⁶⁶ By using an oxygen sensor patch, an immediate and strong decrease in the level of dissolved oxygen was actually revealed by a sharp boost of fluorescence intensity upon UVA illumination in the confined condition (Figure 9). In contrast, the red fluorescence intensity was much lower upon illumination in aerated conditions, as well as in the absence of illumination in both aerated or

confined environments, as expected for oxygen-rich media. The low level of oxygen content in the confined environment might lead to the impossibility for photogenerated electrons to be evacuated through the usual reduction of adsorbed O₂ molecules.⁶⁷ Hence, the photogenerated electrons accumulate in the TiO₂ material, thus reducing Ti⁴⁺ species into Ti³⁺ centers as expected from the redox potential level of Ti³⁺ lower than that of anatase TiO₂.⁶⁶ The resulting TiO₂ structural changes alter the photocatalytic properties.⁶⁶ Besides, the lack of oxygen prevents any free-radical-induced chain scission of (bio)polymers,⁶⁸ which results in the preservation of biopolymers and therefore survival of bacteria upon photocatalytic treatment. Importantly, the presence of bacteria did not enhance the color change despite the O₂ uptake by bacteria for their respiratory activity, probably due to their low consumption of O₂ especially in a non-nutritive medium (NaCl 9 g/L).⁴² It should be noticed that the blue color was more intense in the liquid freshly sterilized by autoclave just before use (e.g. physiological saline water), which is attributed to the removal of the dissolved oxygen. Finally, reduction of Ti⁴⁺ into colored Ti³⁺ is a non-material-dependent phenomenon that occurred similarly on both TiO₂ coatings.

Some ions in the reaction medium were also shown to influence the photocatalytic antibacterial effect. It was especially noticed that 1 h of photocatalytic treatment in M63G medium failed to result in any significant reduction in the “Live” bacteria’s quantity on both TiO₂ coatings (Figure 10), which is very different from the effect in physiological saline medium (Figure 1 B). Complementary experiment of the liquid phase photocatalytic degradation under UVA of methylene blue on the PANaF coatings in the presence or absence of M63G medium confirmed that the M63G medium inhibited the photocatalytic reaction (cf. Figure S22 and its description), even with a M63G medium diluted by 100 times with saline solution. XPS surface analysis (Table S1, Figure S23) revealed the characteristic doublet of P 2p_{3/2-1/2} orbitals for non-polymerized

phosphate species (133.6 eV and 134.5 eV) in the case of the PANaF coating, as the expected consequence of using phosphoric acid as additive for the TiO₂ synthesis ³⁵, while logically no phosphorous was observed in the case of P25 coating (data not shown). After immersion in M63G medium, the P/Ti surface atomic ratio strongly increased for both TiO₂ coatings (Table S1), with the appearance of an additional P 2p_{3/2-1/2} orbital doublet contribution (Figure S23 A, C) similar to that observed on TiO₂-based composites used to adsorb phosphate from wastewater. ⁶⁹ The presence of phosphate deposit was here attributed to phosphate adsorbed from the medium to the coating's surface. It was consequently the probable cause for the suppression of the photocatalytic antibacterial effect. Indeed, Rincon *et al.* reported that phosphate ion is the most detrimental compound among other common ions for the TiO₂ photocatalytic antibacterial effect on *E. coli*. It acts as a poison for the photocatalyst by competing with the oxidizing radicals, by blocking the surface active sites of the photocatalyst ²⁷, and by further serving as a charge recombination center.

4. Conclusion

Photocatalytic antibacterial investigation was conducted under UVA irradiation on a heavy-metals-free P/F-modified TiO₂ coating against several bacterial species in comparison to a reference TiO₂-P25 coating. In general, near-total inactivation of *E. coli* and *S. epidermidis* was obtained, with a clear of both nature and topography of the coating, and of illumination time. Significantly higher efficiency was achieved on the PANaF coating compared to its TiO₂-P25 counterpart. Especially, the smaller size of the PANaF TiO₂ crystals lead to a smoother topography of the coating surface, which may reduce the diffusion length that the photogenerated ROSs must travel to attack the bacterial cell wall. For the first time on TiO₂ coatings, *in-situ* investigation of

the cell wall integrity as well as of the respiratory and intracellular esterase activities showed that the photocatalytic treatment acts on the bacterial cells by attacking the successive barriers of the cell structure, with a decreasing photocatalytic effect as ROSs progress through the cell. Besides, we have evidenced a longer-term, biofilm-preventive effect on *E. coli* and *S. epidermidis* species in good correlation with the immediate photocatalytic antibacterial effect, while complete inactivation was not achieved with *P. fluorescens*, probably due to the capacity of *P. fluorescens* to fight the ROS-induced oxygen stress. In addition, the adsorption of phosphate ions on the TiO₂ surface and the lack of dissolved oxygen in the reaction medium are detrimental to the photocatalytic activity.

Figure 1. (A) Example of fluorescent images of *E. coli* SCC1 bacteria on P25 and PANaF coating

with and without 10 min of illumination. (B) Surface fraction covered by “Live” bacteria with and without 10 min of illumination on P25 and PANaF coating. (C) Surface fraction covered by “Live” (green) and “Damaged” (marked as “Dmg”) (red) bacteria and (D) fraction of “Live” bacteria in the population of *E. coli* SCC1 as a function of the illumination time on reference, P25 and PANaF coatings. Differences compared to $t=0$ are significant ($p\text{-value} < 0.05$) at all illumination length on P25 and PANaF coatings (cf. also in Figure S6).

Figure 2. CAM and CTC stained *E. coli* PHL 628 ⁴¹ quantities for the reference, P25 and PANaF coatings after (A) 10 min and (B) 45 min of UVA illumination. *: Significant differences in CAM stain (p-value < 0.05) compared to “Control”. #: Significant differences in CTC stain (p-value < 0.05) compared to “Control”. *': Significant differences in CAM stain (p-value < 0.05) compared to “P25”. #': Significant differences in CTC stain (p-value < 0.05) compared to “P25”.

Figure 3. (A) XRD patterns of TiO₂ P25 and TiO₂ PANaF. The peak positions and relative intensities for TiO₂ anatase phase (black lines) and rutile phase (red lines), according to the JCPDS cards 21-1272 and 21-1276 respectively, are shown in the bottom of the frame. TEM images of (B) TiO₂ P25 and (C) TiO₂ PANaF powder samples.

Figure 4. (A) Topological micrographs and (C) height profiles of the TiO₂ P25 coating, and (B, D) similar analysis performed on the TiO₂ PANaF coating surfaces, determined by AFM. 3D visualization of the surface topography of the (E) P25 and (F) PANaF TiO₂ coating, with the green

eclipse representing a single bacterium that is shown to scale. Schematic illustration of the contact between one bacterium and both (G) P25 TiO₂ and (H) PANaF coatings, and of the diffusion pattern of ROSs depending on the TiO₂ coating.

Figure 5. (A) Surface fraction covered by “Live” (green) and “Damaged (marked as Dmg)” (red) bacteria and (B) “Live” bacteria fraction of *E. coli* SCC1 after overnight growth in nutritive medium, as a function of the illumination time on control, P25 and PANaF coatings. Significant differences (p -value < 0.05) are true compare to $t=0$ at all illumination length on P25 and PANaF coatings (cf. student study in Figure S13).

Figure 6. Fraction of “Live” bacteria after immediate photocatalytic treatment in the population of (A) *S. epidermidis* ATCC 35983 and (B) *P. fluorescens* ATCC 13525 strains as a function of the illumination time on control, P25 and PANaF coatings. Differences with $t=0$ are significant (p -value < 0.05) at all illumination length on P25 and PANaF coatings (cf. Figures S10 and S11). (C) Fraction of “Live” bacteria in the population of *S. epidermidis* ATCC 35983 (CIP 106510) after overnight growth in nutritive medium, as a function of the previous illumination time on control, P25 and PANaF coatings. Differences with $t=0$ are significant (p -value < 0.05) at 45min illumination length on P25 and PANaF coatings (cf. Figure S15). (D) Example of fluorescent images of *S. epidermidis* and *P. fluorescens* bacteria on P25 and PANaF coating with and without 45 min of illumination.

Figure 7. Illustration of the attack on the Gram-positive and Gram-negative bacteria cell wall by ROSs. The red crossovers from top to bottom represent the cell wall targets to be attacked by the photocatalytically generated ROSs. The detour around PNG layers means that ROSs do not easily degrade it but may bypass this layer thanks to pores.

Figure 8. Immediate photocatalytic antibacterial effect on “Live” *E. coli* SCC1 bacteria adhered on the reference, P25 or PANaF coatings in a confined (oxygen-poor) environment, and with or without UVA illumination for 45 min. No significant differences (p -value < 0.05) noticed between “Live” with or without 45 min of illumination on each coating.

Figure 9. Fluorescent confocal images of an oxygen sensor patch in contact with a PANaF coating (A) in aerated condition, (B) in confined environment within physiological NaCl 9 g/L medium before UVA illumination, and (C) in confined environment within physiological NaCl 9 g/L medium during UVA illumination. (D) Fluorescence background (i.e. control condition) without any microscope laser excitation but with UVA illumination, showed uniform black color. The four photographs were taken at the same sample location.

Figure 10. Immediate photocatalytic antibacterial effect on *E. coli* SCC1 species cultivated in M63G medium ⁷⁰ on P25 and PANAf coatings and with or without 1 h of illumination. No significant differences ($p\text{-value} < 0.05$) are noticed for each coating with or without 1 h of illumination.

Supporting Information. Examples of fluorescent images of bacteria, surface coverage by staining-positive bacteria, supplementary experimental information on studying the effect of phosphate ions adsorption and the lack of oxygen dissolved in the reaction medium on the photocatalytic bactericidal activity of TiO₂ coating.

Author contribution

Yige Yan synthesized the photocatalysts and carried out most of the tests, he also co-designed certain auxiliary experiments on studying the effects of phosphate ions adsorption and the dissolved oxygen concentration on the photocatalytic bactericidal activity of TiO₂ coating. Charline Soraru contributed partially to the microbiological studies.
