Abstract— Characterization of the electromagnetic field emitted by various sources (antenna, radar) is an important issue, either for civil or defense applications. The measurement of the electromagnetic field may be performed by a local probe, the infrared thermography imaging being an alternative way. The latter method, called EMIR [1] (ElectroMagnetic InfraRed) has been used for years at ONERA where it had been developed. We have recently successfully implemented this technique in the domain of visible light, named as EMVI [2] (ElectroMagnetic Visible Imaging). As in EMIR, a thin film (sensitive to either electric field or magnetic field) is heated by the emitted field. But here the film is coated with a polymer doped with fluorescent molecules. As the fluorescent emission depends on the temperature of the film, we achieve a novel thermofluorescent sensor. The results presented here illustrate that new method: both magnetic and electric field imaging of two different radiating systems

Keywords—*Electromagnetism, Thermography, Magnetic losses, Electric losses, Thermo-fluorescence, Meta-material, Zero Order Antenna, High Impedance Surfaces*

I. Introduction

We present in this paper a method for electromagnetic field measurement and imaging in visible wavelengths using fluorophore. In a first step we detail the general principles of this method, then we present measurements of electric and magnetic near field of radiating systems.

In electromagnetic compatibility an issue is the measurement of the electromagnetic field, in particular the near field cartography, to study its interaction with the environment. Strong expansion of the microwave technologies in our environment can be observed for global civil applications (GPS, communications, phone...) or more specific technologies (remote sensing, aeronautics, medicine ...). Interaction between the microwaves and the surrounding environment thus requires a fast method for imaging and measuring the electromagnetic field.

There are different strategies to characterize the electromagnetic field on a large scale. One is to use electromagnetic probes [3, 4] in matrix or with a scanning system. The main disadvantages are the long acquisition time, the intrusive behavior and the large size of the scanning system. Another approach, introduced by Hasegawa [5] in 1995, is to use sensitive films.

We choose an alternative way using thermo-sensitive films which had been developed for infrared thermography method called EMIR (ElectroMagnetic InfraRed). Our objective in the present work is to replace IR thermography by thermo-fluorescence spectroscopy; thus we move to visible range, to improve the spatial resolution of the images.

The film is an electric or magnetic absorbent coated with a thermo-fluorescent layer. In the presence of an electromagnetic field, the energy absorbed by the film is converted into heat, leading to a variation of the fluorescence intensity. The variation of the fluorescence intensity (AFluo) is recorded and post-processed to obtain the incident field. Low frequency modulation of the RF signal, coupled to synchronous demodulation of fluorescence signal, permits to cancel the conduction and convection phenomena that would degrade the field visualization.

II. GENERAL PRINCIPLES

A. Experimental Set-Up

Figure 1 is the schematics of the EMVI setup [6]. The microwave power is modulated at 0.2 Hz. The film is exposed to green LED spot (wavelength: 535 nm). The fluorescence variation is registered by an S-CMOS camera (Dhyana400D 4 Megapixel). The S-CMOS camera is equipped with a low-pass 580 nm filter in order to collect the fluorescence signal.

Figure 1 Thermo-fluorescence imaging setup schematics

B. Thermo-sensitive thin films

We use two kinds of thermo-sensitive films, one sensitive to the electric field and the other sensitive to the magnetic field.

To measure the electric field E , we use a thin film with low-conductivity: $\sigma = 10$ to 100 S/m. The film, a Kapton®-type doped with carbon, has a surface impedance:

$$Z_s = \frac{1}{\sigma e} = 2 \text{ k}\Omega \quad (1)$$

Where σ (S.m⁻¹) the electric conductivity and e (μm) the thickness of the film ($e = 50 \mu\text{m}$ for the Kapton film). The coupling between the electric field and the sensitive thin film generates heat via Joule losses. Under microwave excitation, the Kapton film absorption rate A is related to the surface impedance Z_s [7]:

$$A = \frac{4Z_s Z_0}{(Z_0 + 2Z_s)^2} \quad (2)$$

In our case the absorption rate A is about 15 %, which is large enough to generate a heat variation that is measurable, and weak enough to keep it not intrusive. The density of absorbed power P_{abs} (in W.m⁻³) is related to the electric field by:

$$P_{\text{abs}} = \frac{2Z_s}{e(Z_0 + 2Z_s)^2} E^2 \quad (3)$$

P_{abs} is proportional to the square of the amplitude of the electric field. As the heating is proportional to P_{abs} , we have:

$$|E| = k_E \sqrt{\Delta T_{\text{avg}}} \quad (4)$$

With k_E a constant of proportionality.

To measure the magnetic field H , we use a thin film composed of ferromagnetic micro-particles embedded in polymer matrix. These films are manufactured by TOKIN® Japanese Company [8] for shielding applications. They are electrically insulating and have a good magnetic susceptibility. Depending on the excitation frequency of the magnetic field, two main losses processes can be invoked: at low frequency (typically dc-1 MHz range), hysteresis losses will be responsible for heating with an effective absorption defined by the SAR (specific absorption rate):

$$\text{SAR} = A \cdot f \quad (5)$$

With A the area of the magnetization hysteresis loop (J/g) and f the excitation frequency [9]. Note that A is proportional to the square of the magnetic field amplitude in the low magnetic field regime.

At larger excitation frequency (0.1 to 10 GHz), in the microwave regime, Ferromagnetic Resonance (FMR) losses or precessional losses will take over hysteresis losses. They are related to the imaginary part of the permeability of the ferromagnetic material and the field frequency. Thus the absorbed power P_{abs} (W.m⁻³) is proportional to the square of the magnetic field H :

$$P_{\text{abs}} = \pi f \mu'' H^2 \quad (6)$$

With realistic values of μ'' (10 to 100), e (film thickness: 30 to 300 μm), ~ 1 GHz frequency, we end up with a surface absorbed power ($e \cdot P_{\text{abs}}$) of several percent of the excitation power ($\mu_0 H^2 / 2$), therefore compatible with low intrusiveness of the sensing film.

In summary, the magnetic field amplitude is proportional to the square root of the observed temperature change:

$$|H| = k_H \sqrt{\Delta T_{\text{avg}}} \quad (7)$$

With k_H a constant of proportionality.

C. Thermo-fluorescent Layer

The fluorescence layers are made of Rhodamine B diluted in ethanol and embedded in epoxy resin. Those layers must fulfill the following characteristics: (i) absorption and emission wavelengths have to be discriminated; this is the case for RhB where the emission wavelength is 580 nm and the absorption wavelength is 555 nm. (ii) The fluorescence must depend on temperature; for RhB we have a variation of the quantum yield proportional to the temperature variation, with fluorophore sensitivity of 2 %/K (and this variation is linear from 273 to 393K [10]). (iii) The thickness of the layer must remain below the thermal diffusion length D . We assume that we are in the case of thin film that simplifies the heat equation in 2D:

$$t < D(f_{\text{mod}}) \quad (8)$$

With t the thickness of the film (including the fluorescent coating) and $D(f_{\text{mod}})$ the thermal diffusion length, which depends on the modulation frequency f_{mod} . In our case $D(f_{\text{mod}}) = 50$ to $500 \mu\text{m}$, for $f_{\text{mod}} = 1$ to 0.1 Hz, and $t = 80 \mu\text{m}$ (Kapton + RhB) or $t = 60 \mu\text{m}$ (Token + RhB).

D. Lock-in thermography

We use a lock-in thermography technique [11, 12] to increase the signal to noise ratio of the measurement. This technique permits to avoid continuous thermal effects like natural convection. The microwave power is modulated and the evolution of the temperature can be written as (See Figure 2):

$$T(t) = T_{\text{env}} + \Delta T_{\text{avgmod}} \left(1 - e^{-\left(\frac{t}{\tau}\right)} \right) + \frac{\Delta T_{\text{mod}}}{2} \Pi(f_{\text{mod}}, \varphi) \quad (9)$$

With ΔT_{mod} and Θ the peak to peak amplitude and phase angle of a square function $\Pi(f_{\text{mod}})$ of a duty cycle f_{mod} .

Figure 2 TOKIN-film heating evolution under constant (dotted green line) and 0.2 Hz modulated (blue line) magnetic excitation [6]

We want to extract ΔT_{mod} . A good approximation is

$$\Delta T_{mod} = \frac{P_{abs}e}{\sqrt{4h^2 + (\rho C_p e \omega)^2}} \quad (10)$$

With P_{abs} , h the heat transfer coefficient ($\sim 10 \text{ W.m}^{-2}.\text{K}^{-1}$ for natural convection), ρ the conductivity and C_p the heat capacity.

The modulated signal of fluorescence is proportional to the heat. For example, Figure 3 shows the evolution of the signal of one pixel of the camera. Applying a fast Fourier transform algorithm, we obtain the mean ΔFluo on each pixel and therefore the ΔT_{mod} [13]. Then, E or H amplitude can be deduced from (4) and (7) respectively.

III. ZERO ORDER ANTENNA (ZOR)

A. Introduction

A zero order antenna is made of capacitor and inductor elements which are swapped on the transmission line (See Figure 4) [14]. Microstrips were etched onto a 0.762 mm thick Cu-clad Arlon substrate, with a relative permittivity of 2.55. The spatial period was 2.5 mm, and the line width was about 1.5 mm. We chose interdigitated capacitors to get the series lumped elements, made of eight 100 μm -separated strips, with a surface of about 1.5 mm $\times$ 2 mm. The shunt inductances were 100 μm wide and 13.5 mm long meander lines. They were connected to 2 mm $\times$ 4.8 mm ground

capacitors, in order to avoid vias. It is difficult to make measurements on such system because of its small size.

Figure 4 Zero order antenna schematics

B. Images of electric and magnetic field of ZOR antenna

Images of the electric and magnetic near fields emitted by the ZOR antenna have been achieved. For the measurements, the sensitive films were placed at 2 mm and the microwave frequency was 4.29 GHz.

In Figure 5 we present an image of the electric field (V/m) with $k_E = 603$ (4). The microwave power is 37 dBm (around 8 W). Figure 5 (b) reveals a main emission lobe and Figure 5 (c) secondary lobes. On secondary lobes we can observe the spatial period of the periodic elements of the ZOR. The electric emission is due to the capacitor elements (see Figure 4). In Figure 5 we can observe that the electric field patterns are localized on the capacitor elements.

Figure 5 (a) Image of electric field of ZOR antenna at 4.29 GHz, (b) profile of the main lobe (white dotted), (c) profile of the secondary lobes (red dotted)

Figure 6 represents the square root of ΔT_{mod} , therefore proportional to the magnetic field (7). We thus obtain magnetic field image and profile. The microwave power is 38 dBm (around 6 W). Figure 6 also reveals a main emission lobe and secondary lobes. On the secondary lobes we observe the spatial period of the periodic capacitor and inductor elements. As the magnetic emission is due to the

inductor elements, we can observe in Figure 6 the magnetic near field pattern localized on those elements.

Figure 6 (a) Demodulated image of the magnetic field of ZOR antenna at 4.29 GHz, (b) Profile (red dotted)

IV. HIGH IMPEDANCE SURFACE (HIS)

A. Introduction

HIS is a special passive electromagnetic structure (based on metamaterial technology) designed for reducing mutual coupling between patches antennas (for applications where size constraints are crucial: space systems for example).

Figure 7 Simulation setup of the HIS embedded in the transmission line and picture of the realized structure [15]

Figure 7 shows how the HIS cells are located between the ground plane and the transmission line [16]. It is made of periodic elements consisting of two layers dielectric substrate. The first dielectric layer includes a ground plane on the bottom face. The second layer is made of the same material as the first. This layer is printed on its two faces with copper. On the bottom face there are hexagon shape pattern and on the top face, equilateral triangle shape pattern with metallic via to connect the ground plane. The HIS is therefore composed of periodic capacitive and inductive

elements. We can simply model HIS by a LC parallel circuit.

B. Images of electric field of HIS

We present in this section images of electric and magnetic field of HIS for a range of frequencies from 1GHz to 1.8GHz. Figure 8 shows the experimental setup for this measurement.

Figure 8 Experimental setup for the measurement of the magnetic field of the HIS

Figure 9 presents the measured S_{12} parameter with and without the film [15]. It can be observed that the band gap frequencies are conserved with the presence of the sensitive-film. So we can conclude that the film is non-intrusive. We can observe two cut-off frequencies at 1.3 GHz and 1.9 GHz (EMVI measurements will therefore be achieved for the first cut-off frequencies).

Figure 9 S_{12} measurement of the HIS, with and without the thermo-emissive film [15]

Figure 10 shows the amplitude of the field (V/m) on the HIS line, for different frequencies (from 1 to 1.8 GHz Figure 10):

Figure 10 Electric field patterns at different frequencies

The Figure 10 exhibits different behaviors of the HIS depending on the frequency: at passing frequencies (1 GHz for example), the electric field appears along the line ; for a cut-off frequency (at 1.35 GHz), a resolution behavior arises and HIS cells resonate: subwavelength details of the electric near field are thus exhibited. We can note that visualizing these sub-wavelength details would have been impossible with a local probe.

Figure 11 shows the evolution of the amplitude of the field at the output side of the transmission line (corresponding to the red cross - $x = 10$, $y = 60$ -, on the left of the Figure 10. We obtain a good agreement with the S_{12} measurement presented in Figure 9.

Figure 11 Output electric field on the HIS as a function of the frequency

C. Images of magnetic field of HIS

In this section, we present qualitative images of the magnetic field. Indeed, it was difficult to obtain a quantitative measurement because of the uncertainty of the ferromagnetic film properties (that are needed to evaluate the k_H factor of the (7)). Images presented in Figure 12 although represent the square root of ΔT_{mod} , therefore proportional to the magnetic field (7). As previously, we observe a passing behavior at 1.1 GHz and a resonant behavior at 1.3 GHz.

Figure 12 Magnetic field patterns at two frequencies

V. CONCLUSION

In this paper we presented characterization of two radiating systems using EMVI method. We exhibit complex near field pattern produced by ZOR antenna and HIS metamaterial structure. For ZOR antenna, electric and magnetic field patterns of the whole structure have been obtained for one frequency and one microwave power. For the HIS structure, electric field patterns have been obtained for a frequency range from 1 GHz to 1.8 GHz (first bandgap regions) and the magnetic field have been obtained for two frequencies (one in bandwidth and one in bandgap regions).

For ZOR antenna, the patterns show the behavior of the capacitor and inductor periodic elements. For HIS structure the electric patterns show how this structure behaves in the frequency range, more especially in the first bandgap regions. Image of magnetic field of HIS show the resonance of the HIS cells at 1.3 GHz.

We thus show that we can visualize complex near field by thermos-fluorescence. These kinds of field images are

difficult to obtain by experimental usual methods (EM probes) or even by simulation. In the future we shall be able to distinct the components of the field, using anisotropic films.
