ABSTRACT

The Cook-Austral volcanic lineament extends from Macdonald seamount (east) to Aitutaki Island (west), and comprises hotspot-related volcanic islands, seamounts, and atolls. The Cook-Austral have been characterized as multiple overlapping, age-progressive hotspot tracks generated by at least two mantle plumes, including the Arago and Macdonald plumes, which have fed volcano construction for ~20 m.y. The Arago and Macdonald hotspot tracks are argued to have

been active for at least 70 m.y., and to extend northwest of the Cook-Austral into the Cretaceous-aged Tuvalu-Gilbert and Tokelau Island chains, respectively. Large gaps in sampling exist along the predicted hotspot tracks, complicating efforts seeking to show that the Arago and Macdonald hotspots have been continuous, long-lived sources of hotspot volcanism back into the Cretaceous. We present new major and trace element concentrations, and radiogenic isotopes for three seamounts (Moki, Malulu, Dino) and one atoll (Rose), and new clinopyroxene $^{40}\text{Ar}/^{39}\text{Ar}$ ages for Rose (24.81 ± 1.02 Ma) and Moki (44.53 ± 10.05 Ma). All volcanoes are located in the poorly sampled region between the younger Cook-Austral and the older, Cretaceous portions of the Arago and Macdonald hotspot tracks. Absolute plate motion modeling indicates that the Rose and Moki volcanoes lie on or near the reconstructed traces of the Arago and Macdonald hotspots, respectively, and the $^{40}\text{Ar}/^{39}\text{Ar}$ ages for Rose and Moki align with the predicted age progression for the Arago (Rose) and Macdonald (Moki) hotspots, thereby linking the younger Cook-Austral and older Cretaceous portions of the long-lived (>70 m.y.) Arago and Macdonald hotspot tracks.

INTRODUCTION

Intraplate volcanism is thought to result from buoyantly upwelling mantle plumes that partially melt beneath a moving plate, thereby producing age-progressive “hotspot” volcanism (e.g., Morgan, 1971). Some plume-derived volcanic chains, such as the Hawaii-Emperor (North Pacific) and Louisville (South Pacific) chains, are well-defined with clear age progressions extending back to ~ 80 Ma (Sharp and Clague, 2006; O’Connor et al., 2013; Koppers et al., 2012). The Cook-Austral volcanic lineament in the South Pacific Ocean (Cook-Austral hereafter) is the manifestation of at least two overlapping hotspot tracks—the Arago (also referred to as “Rurutu”, or “Atiu trend”) and Macdonald hotspot tracks. Denser sampling may reveal that not all seamounts

along the predicted path of the Cook-Austral hotspots relate to these hotspots, but samples from two seamounts presented in this study strengthen hotspot age progressions anchored by young volcanism at Macdonald and Arago seamounts, respectively (Figure 1; Turner and Jarrard, 1982; Chauvel et al., 1997; Bonneville et al., 2002; Finlayson et al., 2018; Konrad et al., 2018; Rose and Koppers, 2019). While Cook-Austral volcanism has been argued to be relatively short-lived (0-20 m.y.; Chauvel et al., 1997; Lassiter et al., 2003), there is growing evidence that the mantle plumes responsible for Cook-Austral volcanism are long-lived features responsible for generating Pacific seamounts during the Cretaceous (Staudigel et al., 1991; Koppers et al., 2001; 2003; 2007; Konter et al., 2008; Finlayson et al., 2018; Konrad et al., 2018).

Using absolute plate motion models, Koppers et al. (2003; 2007) and Konter et al. (2008) showed that Cretaceous Pacific island chains, including the Tokelau and Tuvalu-Gilbert chains, were located over the Macdonald and Arago mantle plumes, respectively (Figure 1). Konter et al. (2008) also showed geochemical similarities between the Cretaceous and Cook-Austral portions of these two hotspot tracks, strengthening the link between the younger and older segments of these hotspot tracks. Recently, Finlayson et al. (2018) and Konrad et al. (2018) showed that the Tuvalu chain captures the 50 Ma “bend” (temporally and morphologically similar to the Hawaii-Emperor Bend) of the proposed Arago hotspot, thereby strengthening the link between the younger Cook-Austral and older Cretaceous segments of this proposed long-lived hotspot. However, volcanoes sampling the 10-45 Ma portion of the Arago hotspot represent an uncharacterized gap in the hotspot track. In contrast to the Arago hotspot, the Hawaii-Emperor Bend portion of the proposed Macdonald hotspot track has not yet been identified, and it will be important for linking the more recent Cook-Austral and older Cretaceous Tokelau segments of this hotspot track. Thus, while there is growing evidence that the Macdonald and Arago hotspots have been active since at

least ~70 Ma, critical gaps in sampling and characterization of these two hotspot tracks weaken the hypothesis for long-lived, continuous volcanism.

Volcanoes in the region of the Samoan hotspot track, located ~1,000 km WNW of Aitutaki Island, were found to exhibit geochemical signatures inconsistent with nearby Samoan volcanoes (Jackson et al., 2010). Termed “interlopers” (i.e., not belonging in the region: Jackson et al. 2010), these volcanoes (Rose atoll and two seamounts, Malulu and Papatua) yielded samples exhibiting significant alteration and thick ferromanganese coatings, which contrast with the young, fresh lavas from Samoan volcanoes in the region. These interloper volcanoes also exhibit geochemical signatures consistent with an origin over Cook-Austral hotspots, which lie on, or close to, the reconstructed Macdonald and Arago hotspot traces.

We targeted the region between the Samoan hotspot and the Cook-Austral for additional sampling on the NOAA ocean exploration cruise EX1702 aboard the *Okeanos Explorer* in February/March 2017. Four volcanoes were sampled (Rose atoll and Malulu, Moki, and Dino seamount) by ROV (Remotely Operated Vehicle; Figure 1; Tables S1 and S2 in the Supplemental Material¹). Descriptions and thin section images are publicly available for all EX1702 samples used in this study (osu-mgr.org/noaa-ex1702). We present new Sr-Nd-Pb-Hf isotopic data (Figures 2, S1) and major and trace element concentrations (Figure S2) on these volcanoes. The new geochemical and geochronological data, in conjunction with previously published geochemical data for two legacy samples from Rose atoll and one legacy sample each for Malulu and Papatua seamounts (obtained by deep-sea dredging; see Supplemental Materials and Jackson et al. (2010)), show that the Moki and Rose volcanoes provide “missing links” between younger Cook-Austral and older Cretaceous segments of the Macdonald and Arago

hotspots, respectively. These links extend the longevity of the Arago and Macdonald hotspots to at least 70 Ma, making them two of the longest-lived hotspots in the Pacific.

RESULTS AND DISCUSSION

Sample collection and analytical protocols for analysis of igneous material from Rose atoll and the Malulu, Moki, and Dino seamounts are detailed in the Supplemental Materials. Due to the typically high degrees of submarine alteration, fine-grained to glass-rich groundmasses and/or absence of traditionally dated phenocrystic phases (e.g. plagioclase), ages were not available for whole rock samples from these five volcanoes; nonetheless, with extensive acid leaching, we could obtain radiogenic isotopic compositions on these samples (see Supplemental Materials). However, new advancements in $^{40}\text{Ar}/^{39}\text{Ar}$ methodology permit age determinations from clinopyroxene phenocrysts (Konrad et al., 2019). Using this technique, we successfully dated lava flows from the Moki and Rose volcanoes. The clinopyroxene separates from Rose Atoll (sample AVON2/3-D66-1) and Moki Seamount (sample EX1702-D7-2) both produced age spectrums that meet standard $^{40}\text{Ar}/^{39}\text{Ar}$ criteria, where plateaus include $> 60\%$ of the $^{39}\text{Ar}_{(\text{K})}$ and probability of fit (P) values $> 5\%$. Two experiments for AVON2/3-D66-1, carried out on two clinopyroxene size fractions, produced concordant plateaus, which allows for the results to be combined and averaged (Figure S3). The $^{40}\text{Ar}/^{36}\text{Ar}$ intercept values are within uncertainty of atmosphere (298.6), supporting the plateau age of 24.81 ± 1.02 Ma (2σ). This age places Rose atoll squarely on the age-progression for the Arago hotspot (Figure 3), which is consistent with the observation that Rose is near the reconstructed trace of the Arago hotspot (Figure 1). Sample EX1702-D7-2 contained low concentrations of potassium derived ^{39}Ar and radiogenic ^{40}Ar , resulting in large uncertainties. The experiment produced a long plateau with a slightly higher-

than- atmospheric $^{40}\text{Ar}/^{36}\text{Ar}$ intercept value of 313 ± 12 (2σ). Therefore, the inverse isochron age determination is preferred at 44.53 ± 10.05 Ma (2σ) (Figure S3, Tables S3,S 4). While uncertainties are large, the Moki seamount age places it on the Macdonald hotspot age progression (Figure 3).

New geochemical data are presented in Tables S1 and S2. In radiogenic isotopic space, Macdonald and Arago seamounts sample HIMU (high ‘ μ ’, or high $^{238}\text{U}/^{204}\text{Pb}$), EM (enriched mantle) and geochemically-depleted endmembers (Chauvel and Vidal, 1992; Chauvel et al., 1997; Lassiter et al., 2003; Hanyu et al., 2013) that may reflect a contribution from a C (Common; Hanan and Graham, 1996) or FOZO (Hart et al., 1992) component (Konter et al., 2008; Figures 2, S1). While Rose atoll is erupted over the Arago hotspot, whole rock (Jackson et al., 2010) and glass geochemistry do not consistently plot in the fields for Arago hotspot volcanoes in the Cook-Austral volcanic lineament or the older portion of the Arago hotspot (Gilbert, Tuvalu, Marshall, and Wake islands and seamounts), and in some isotope spaces one or multiple Rose samples plot only in the field for Macdonald hotspot volcanoes (Figures 2, S1).

The Moki Seamount sample yielded an age with greater uncertainty, but the age is nonetheless consistent with a Macdonald hotspot origin, and the Moki sample consistently falls in a region of isotopic space that overlaps with Macdonald hotspot volcanoes (Figures 2, S1). In the hotspot reconstruction using the Wessel and Kroenke (2008) absolute plate motion model, Moki plots significantly closer to the reconstructed trace of the Macdonald hotspot track than the Arago hotspot track, consistent with the geochronological and geochemical data above (Figure 1). While uncertainties are large, the Moki seamount age places it on the Macdonald hotspot age progression (Figure 3), and the age for Moki overlaps with the reconstructed Macdonald hotspot track, even at the 1σ level.

The Dino Seamount sample and the new Malulu Seamount sample presented here (EX1702-D12-5) consistently plot in the field for Macdonald hotspot volcanoes in the Cook-Austral volcanic lineament, but age data are needed before a Macdonald hotspot designation can be assigned. Papatua seamount (Jackson et al., 2010) plots in a region that overlaps the Macdonald and Arago hotspots in all isotopic spaces for which there are available data except for the $^{206}\text{Pb}/^{204}\text{Pb}$ vs $^{143}\text{Nd}/^{144}\text{Nd}$ isotope space where it plots in the Macdonald field (Figure 2 and Figure S1). Unfortunately, Papatua is also geographically located on a portion of the reconstructed hotspot tracks where the Macdonald and Arago tracks overlap, preventing a hotspot designation for Papatua. Age data are needed to determine the hotspot origin of this seamount.

The link between the younger Cook-Austral and older Cretaceous segments of the Macdonald and Arago hotspots provided by samples from Moki seamount and the Rose atoll, respectively, has two key implications: 1) it allows us to posit, with greater confidence, that the Macdonald hotspot is both continuous and long lived and 2) it supports previous arguments for the longevity of the Arago hotspot (Finlayson et al., 2018). Thus, the Macdonald and Arago hotspots join Hawaii (Tarduno et al., 2003; O'Connor et al., 2013) and Louisville (Lonsdale, 1998; Koppers et al., 2012) as two Pacific hotspots whose activity has been mapped for least 70 m.y.

An important outcome of this work is in strengthening the case for the longevity of the Arago and Macdonald hotspots. However, it is becoming increasingly clear that the Arago and Macdonald hotspots show significant overlap in Sr-Nd-Pb-Hf isotopic space, and it is the combination of geochemistry and ages that uniquely constrains which hotspot a given seamount belongs to. For example, the Arago and Macdonald plumes have consistently sampled the most extreme HIMU compositions ($^{206}\text{Pb}/^{204}\text{Pb}$ up to 21.42 for Arago, and 21.93 for Macdonald; Figure 2) in the Pacific since the Cretaceous (Konter et al., 2008; Hanyu et al., 2011; Finlayson

et al., 2018). The reason for this may be due to the close proximity of the two hotspots: the long-lived Arago hotspot is located just ~1200 km WNW from the Macdonald hotspot. If both hotspots are fed by mantle plumes that emerge from the core-mantle boundary, the plume conduits are separated by only ~660 km at the core mantle boundary. Thus, the regions (i.e., “feeding zones”) at the core mantle boundary that are sourcing material to the upwelling Macdonald and Arago plumes may overlap, explaining the similar isotopic signatures at both hotspots (Figure 2). If both plumes have been producing active volcanism for >70 m.y., an important dynamical question to be addressed is how the two closely-spaced plume conduits have interacted over geologic time (Lassiter et al., 2003). Both plumes arise from the large low shear-wave velocity province (LLSVP) situated on top of the core-mantle boundary beneath the Pacific (Jackson et al., 2018), and long-lived HIMU signatures in both plumes might suggest this is a geochemical characteristic of the region of the Pacific LLSVP that is sourced by both plumes.

Rose-Koga acknowledges support from Laboratory of Excellence ClerVolc (Clermont-Ferrand Centre for Volcano Research). This is Laboratory of Excellence ClerVolc contribution number 438.

Figure Captions

Figure 1. Map of the current Cook-Austral, Tokelau, and Tuvalu-Gilbert seamounts and volcanoes (South Pacific Ocean) pertaining to this study, showing reconstructed tracks for the Samoan and Cook-Austral hotspots (including Macdonald and Arago hotspots). Shaded bands anchored to the active portions of each hotspot track are reconstructed traces for each hotspot track (dark blue=Macdonald, red=Arago, yellow=Rarotonga, purple=Samoa), and are based on the Wessel and Kroenke (2008) absolute plate motion model; stars mark proposed hotspot locations. Blue circles represent volcanoes previously associated with the Macdonald hotspot and red circles represent volcanoes previously associated with the Arago hotspot (data sources are from the following: Koppers et al., 2007; Konrad et al., 2018; Rose and Koppers, 2019; Jackson et al., 2020). The five interloper volcanoes investigated in this study—Moki, Malulu, Rose, Dino, and Papatua—are also indicated in the map.

Figure 2. $^{143}\text{Nd}/^{144}\text{Nd}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$ for volcanoes in this study plotted with existing data from Macdonald and Arago hotspot-related volcanoes. The Moki and Malulu isotopic data produced for this study are from clinopyroxene phenocrysts, as seawater alteration prevented the analysis of whole rock samples. New data also include pillow rim glass analyses from Rose atoll, whole rock data from Dino seamount, and previously-published whole rock data on Rose, Malulu, and Papatua lavas from Jackson et al. (2010). The younger portions of the Arago (red field) and Macdonald (blue) hotspots in the Cook-Austral volcanic lineament are distinguished from the older portions of these hotspots (light grey with long dashed lines for the Tuvalu, Gilbert, Marshall and Wake islands and seamounts [i.e., Old Arago]; dark grey with short dashed lines for the

Tokelau Islands and seamounts [i.e., Old Macdonald]). Age-corrected (to the time of eruption) isotopic values are shown, but only where ages are available (Moki, and Rose atoll). The three undated Rose samples are assumed to have the same age as sample EX1702-D3-2. The isotopic shift due to the age correction is shown by the line extending from the respective datapoints (which represents the magnitude and direction of the age correction). The other samples (Malulu, Papatua, and Dino) are not associated with ages and age corrections are not provided. All data not produced in this study was previously published and downloaded from the Georoc database (<http://georoc.mpch681mainz.gwdg.de/georoc>). HIMU—high μ = high $^{238}\text{U}/^{204}\text{Pb}$; EM1-EM2—enriched mantle sources. Figure is modified after Jackson et al. (2020).

Figure 3. Hotspot track age-distance plot showing Rose and Moki volcanoes (South Pacific Ocean), including volcanoes associated with the Macdonald, Arago, Rarotonga, and Samoa trends plotted along their respective reconstructed hotspot track. The clinopyroxene incremental heating $^{40}\text{Ar}/^{39}\text{Ar}$ ages for Rose and Moki are labeled (and shown with 2σ uncertainties). Great circle distances from the active hotspots are used. The Wessel and Kroenke (2008) absolute plate motion model, used to model volcanic age progressions, is shown for each hotspot (blue=Macdonald, red=Arago, black=Rarotonga, and pink=Samoa). Estimates for the uncertainty in the Wessel and Kroenke (2008) model are also provided (dashed lines). Ages for the Tokelau and Tuvalu-Gilbert volcanoes were published by Staudigel et al. (1991), Koppers et al. (2003) Konter et al. (2008), Finlayson et al. (2018), and Konrad et al. (2018). Ages for the Cook-Austral volcanic lineament are compiled in Jackson et al. (2020) and Rose and Koppers (2019).

Supplemental Materials

Methods

Sample locations, preparation and wet chemistry.

The samples in this study were collected by deep submarine dredging from four seamounts (Papatua, Moki, Seamount D [“Dino”], Malulu) and one atoll (Rose) in the Samoan region. Several samples in this study were collected during the 2017 expedition (EX1702) aboard the NOAA *Okeanos Explorer*: Moki seamount (basaltic sample D7-2), Dino seamount (basaltic sample D11-1), Rose atoll (pillow fragment sample D3-2), and Malulu seamount (hyaloclastite sample D12-5). Finally, two samples from the 1999 AVON2/3 expedition aboard the R/V Melville which were previously characterized are presented here with modern Pb-isotopic analyses: AVON2/3-D67-11 from Malulu seamount which is an altered basalt, and basaltic sample AVON2/3-D66-1 from Rose atoll. Tables S1 and S2 present previously published data on these two Rose samples in addition to two other samples—AVON2/3-D65-18 (from Malulu seamount) and ALIA-DR129-05 (from Papatua seamount)—from non-Samoan seamounts in the Samoan region. Sample locations and geochemical characterization of these four previously published lavas can be found in **Jackson et al. (2010)**.

Samples were crushed in plastic bags to avoid exposure to metal. Crushed material was then sieved. For two samples (EX1702-D12-5 hyaloclastite from Malulu seamount and EX1702-D7-2 basalt from Moki seamount), clinopyroxene was removed for radiogenic isotopic work due to the lack of fresh basaltic material. For Rose atoll sample EX1702-D3-2, volcanic glass was removed from the pillow rim for radiogenic isotopic analysis (this glass was also characterized for major and trace element compositions, but we also present whole rock major and trace element data for this sample as well). For sample EX1702-11-1 (Seamount D), 200 mg of the freshest (0.5 to 1 mm) rock chips were analyzed, targeting groundmass. We also separated the freshest groundmass chips from two previously characterized lavas—AVON2/3-D66-1 (Rose atoll) and AVON2/3-D67-11 (Malulu seamount)—for a new characterization using modern Pb isotopic analyses and new analyses of Sr and Nd isotopes on the same material.

The groundmass samples (including the EX1702-D3-2 glass) were treated with a heavy leaching protocol described in **Price et al. (2016)** which, in addition to the 6N HCl leaching treatment, uses hot 4N HNO₃ and hot 30% H₂O₂. The clinopyroxene samples were first leached in concentrated HCl for 1 hour at 40° C, then in concentrated nitric for 1 hour at 40° C, with ~1 hour of sonication in the same acid following each leaching step; after this initial leach, the clinopyroxenes were subjected to the same “heavy leaching” as the groundmass and glass samples (and, following leaching, only pristine clinopyroxenes were selected for dissolution and analysis). Note that replicated analysis of the D11-1 groundmass followed additional leaching: it was treated with the strong leaching protocol followed by an additional 8 hours of leaching in 6N HCl at 60° C and an additional 10 minutes leaching in cold concentrated HF; this may explain the offset in Sr, Nd, and Pb isotopes between the original and replicate rounds of analyses of this sample. USGS reference materials were not leached. Following leaching, samples were rinsed and sonicated repeatedly in MilliQ H₂O (≥ 18.2 M $\Omega \cdot$ cm deionized water). Sample dissolution, wet chemistry (including Sr, Pb, Hf and Nd elemental separations), and mass spectrometry was carried out in one of the three following institutions:

1. One batch of samples underwent Sr, Nd, and Pb chemical separations at UCSB, with Sr and Nd isotopes analyzed on the UCSB TIMS and Pb isotopes analyzed on the WHOI

MC-ICP-MS; the wet chemistry follows methods developed in **Price et al. (2014)** with modifications as follows: Following dissolution in concentrated HF and HNO₃, Sr and Pb were purified by two passes through 100 µL of Eichrom Sr resin (25-50 µm), and Nd purified was purified from the wash of the Sr resin using a two-step method employing Eichrom TRU resin (100-150 µm) followed by Eichrom LN-Spec resin (50-100 µm). Total procedural blanks are <200 pg for Sr, <50 pg for Nd, and < 120 pg for Pb.

2. A second batch of samples underwent Sr, Nd, and Pb chemical separations at UCSB as described above, with Sr and Nd isotopes analyzed on the UCSB TIMS. However, Pb isotopes were analyzed on the University of South Carolina MC-ICP-MS.
3. A third batch of samples, which included just the cpx separates for EX1702-D12-5 and EX1702-D7-5, underwent dissolution, chemical separations (for Sr, Nd, Hf, and Pb), and mass spectrometry at the University of South Carolina.

Further description of wet chemistry and mass spectrometry is provided below.

Sr and Nd mass spectrometry at UCSB and Pb mass spectrometry at WHOI.

Sr and Nd isotopes were analyzed on a Thermo Triton Plus TIMS mass spectrometer housed at UCSB. 500 ng of Sr or Nd was loaded on outgassed, zone-refined Re (99.999% purity, H-Cross, USA) filaments. With the exception of the first ⁸⁷Sr/⁸⁶Sr analyses (EX1702-D12-5 clinopyroxene, EX1702-D7-5 clinopyroxene, EX1702-D11-1, EX1702-D3-2) and associated standards, which used a 33 picoamp gainboard but did not employ amplifier rotation, all other Sr and Nd isotopic analyses of samples, replicates, and associated standards employed amplifier rotation on 10¹¹ ohm amplifiers and a 3.3 picoamp gainboard. Gains were run with the start of a new barrel. Approximately 20% of analysis time was devoted to baselines: baselines are taken with each rotation of the amplifiers (i.e., because 5 amplifiers-cup pairs were used during analyses, 5 baselines were taken during each full amplifier rotation). Intensities were kept at approximately 3V on mass 88 and 3V on mass 144 during ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd analyses, respectively. Sr and Nd isotopes were corrected for mass bias assuming an exponential law and using canonical ⁸⁶Sr/⁸⁸Sr and ¹⁴⁶Nd/¹⁴⁴Nd ratios of 0.1194 and 0.7219, respectively. Isobaric interferences from Rb and Sm were corrected by monitoring masses 85 and 147, but corrections to the ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd ratios were nominal. USGS reference materials (processed through all steps of wet chemistry and column chemistry with unknowns at UCSB) and sample unknowns were corrected for the offset between preferred and measured standard (NBS987 or JNdi) values with each barrel: preferred value for NBS987 ⁸⁷Sr/⁸⁶Sr is 0.710240, and JNdi is 0.512099 (**Garçon et al., 2018**). On the UCSB Triton Plus the average ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd and long-term reproducibility, up to and including this study, of NBS987 and JNdi using amplifier rotation is 0.710246 ± 0.000011 (2SD, N=29) and, 0.512100 ± 0.000004 (2SD, N=27), respectively. The corresponding average ⁸⁷Sr/⁸⁶Sr and long-term reproducibility when analyzing NBS987 without amplifier rotation is 0.710244 ± 0.000014 (2SD, N=39).

We note that prior analyses of the AVON2/3 cruise samples from Rose (AVON2/3-66-1) and Malulu (AVON2/3-67-11), reported in **Jackson et al. (2010)**, should be replaced by new analyses of these two samples shown in **Table S1**, for two reasons: 1) the previously published Pb isotopic analyses were made by TIMS without a spike addition to control for in-run mass fractionation and 2) these two samples exhibit significant alteration and acid leaching for the prior analyses may not have been sufficient to have removed alteration phases. We note that the new ¹⁴³Nd/¹⁴⁴Nd analysis for AVON2/3-67-11 (0.512982) shows significant disagreement with the prior analysis (0.512796, after correction to the JNdi reference frame use here by applying

the La Jolla to JNdi conversion from **Tanaka et al., 2000**) made at WHOI in the year 2000 and reported by **Jackson et al. (2010)**. In order to evaluate the accuracy of the new $^{143}\text{Nd}/^{144}\text{Nd}$ measurement, three additional aliquots of this sample were obtained from the WHOI dredge repository, including the original bag of crushed rock chips for this sample from which material was extracted for the 2000 analysis (see AVON2/3-67-11 rep1, rep2, and rep3 in **Table S1**); new batches of chips were prepared by separately crushing each aliquot, and the different aliquots of chips were leached and underwent wet chemistry and mass spectrometry during a separate session than the original analyses. The three replicate $^{143}\text{Nd}/^{144}\text{Nd}$ analyses (0.512982, 0.512980, and 0.512981) show excellent agreement with the new $^{143}\text{Nd}/^{144}\text{Nd}$ result, confirming its accuracy. We note that the new analyses of Sr and Pb isotopes for this sample are similar to the published data for this sample reported in **Jackson et al. (2010)**.

Using the Pb fractions purified at UCSB, Pb isotopic analyses were carried out at the Woods Hole Oceanographic Institution using the Thermo Neptune MC-ICP-MS housed there (**Hart and Blusztajn, 2006**). Fractionation correction was made by Tl-addition assuming an exponential fractionation law (**White et al., 2001**). Samples and an aliquot of AGV-2 (processed through all steps of column chemistry and mass spectrometry with the samples) were corrected for the offset between preferred (i.e., values from **Eisele et al., 2003**) and measured ratios of NBS981.

For a different subset of samples (specified in **Table S2**), Pb fractions purified at UCSB were carried out at the University of South Carolina on Thermo Neptune MC-ICP-MS housed there. The samples, together with an aliquot of BCR-2 (processed through all steps of column chemistry and mass spectrometry with the samples) were corrected for the offset between preferred (i.e., values from **Eisele et al., 2003**) and measured ratios of NBS981.

Sr, Nd, Hf and Pb isotopic and major and trace element concentrations on clinopyroxenes from samples EX1702-D12-5 and EX1702-D7-5 at U. South Carolina.

Following leaching, visually fresh clinopyroxenes were picked under a binocular microscope. The clinopyroxene samples were then processed at the Center for Elemental Mass Spectrometry, University of South Carolina. Approximately 150-200 mg of sample was first leached (using the same protocol described above) and dissolved in Teflon distilled HF:HNO₃ (3:1) mixture on a hot plate for ~ 3 days, with frequent sonication. After drydown the samples were picked in 6N HCl with added boric acid in 10N HCl to complex fluorides, which increases yields in Hf chemistry (**Frisby et al., 2016**). Afterwards the samples were converted to nitrates. A small aliquot (~5%) was taken for Sr and Nd isotopes and the remainder was dried down with HBr for Pb and then Hf chemistry. A precisely determined aliquot of the dissolved clinopyroxene samples was pipetted from the solution and gravimetrically diluted for trace element analyses prior to the splitting of Sr-Nd and Pb-Hf fractions. Trace elements were then analyzed by ICP-MS with an aliquot of BHVO-1 on the Element2 following established methods for the lab (e.g. **Frisby et al, 2016**).

For the chemical separations, Sr was separated first on an Eichrom Sr-spec resin and the washes containing the rest of the elements were processed through an Eichrom TRU spec resin to concentrate the LREEs, and then on an Eichrom Ln-Resin to isolate Nd (**Frisby et al, 2016**). The Pb was separated on anion resin in HBr and HCl media, and the washes from that were processed for Hf following the method of **Munker et al. (2001)**. An unleached BCR-2 powder was dissolved and processed through all steps of chemistry and mass spectrometry with sample unknowns. Total procedural blanks during the analytical session were 10 pg for Pb, 180 pg for

Sr, <10 pg for Nd, and 40 pg for Hf.

The isotopic compositions of Sr, Nd, Pb, and Hf were measured on the Thermo Neptune housed at the University of South Carolina following methods provided in **Beguelin et al., (2017)**. All samples were corrected for mass bias using the exponential law: Pb was corrected using the Tl addition method (**White et al., 2001**), $^{87}\text{Sr}/^{86}\text{Sr}$ was corrected using $^{86}\text{Sr}/^{88}\text{Sr}$ of 0.1194, $^{143}\text{Nd}/^{144}\text{Nd}$ was corrected using $^{146}\text{Nd}/^{144}\text{Nd}$ of 0.7219, and $^{176}\text{Hf}/^{177}\text{Hf}$ was corrected using $^{179}\text{Hf}/^{177}\text{Hf}$ of 0.7325. All isotopic data on samples were corrected for the offset between measured and preferred standards using the following preferred values: SRM981 values from **Eisele et al. (2003)** ($^{206}\text{Pb}/^{204}\text{Pb} = 16.9409$, $^{207}\text{Pb}/^{204}\text{Pb} = 15.4976$, and $^{208}\text{Pb}/^{204}\text{Pb} = 36.7262$); NBS987 $^{87}\text{Sr}/^{86}\text{Sr}$ value of 0.710240; JMC-475 $^{176}\text{Hf}/^{177}\text{Hf}$ value of 0.282160; JNdi $^{143}\text{Nd}/^{144}\text{Nd}$ value of 0.512099 (**Garçon et al., 2018**).

During the course of these measurements, reproducibility of $^{87}\text{Sr}/^{86}\text{Sr}$ on NBS987 was 22 ppm, of $^{143}\text{Nd}/^{144}\text{Nd}$ on JNdi-1 was 20 ppm, of $^{176}\text{Hf}/^{177}\text{Hf}$ on JMC-475 was 28 ppm, and Pb isotopic compositions on NBS981 were 62ppm on $^{206}\text{Pb}/^{204}\text{Pb}$, 68 ppm for $^{207}\text{Pb}/^{204}\text{Pb}$, and 80 ppm for $^{208}\text{Pb}/^{204}\text{Pb}$ (all 2SE). An unleached BCR-2 powder was run together with the clinopyroxenes through all steps of column chemistry and mass spectrometry, and data are shown in **Table S1**.

Whole rock major and trace element analyses at Washington State University.

For samples EX1702-D7-2, EX1702-D3-2, and EX1702-D11-1, 10 to 20 g blocks of rock were cut with the rock saw, and care was taken to avoid visibly altered portions of rock. The blocks were cleaned with silicon carbide sand paper, and sonicated in MilliQ H₂O. Samples were crushed and then powdered in an agate shatterbox (with cleaning with silica between barrels) at the Geoanalytical lab at the Washington State University (WSU). Major and trace element concentrations were obtained at WSU by X-ray fluorescence (XRF) and ICP-MS. XRF and ICP-MS methods, and evaluation of accuracy using international standards, are reported elsewhere (**Knaack et al., 1994; Johnson et al., 1999**), but summarized briefly here. The precision (1 σ) for major elements in basalts by XRF is 0.11–0.33% (1 σ) of the amount present for SiO₂, Al₂O₃, TiO₂, P₂O₅) and 0.38–0.71% for other elements. Trace element precision of basalts by ICP-MS is 0.77–3.2% (1 σ) for trace elements except for U (9.3%) and Th (9.5%). An aliquot of the USGS reference material BCR-2 was analyzed as an unknown together with the basaltic unknowns, and the data are reported in **Table S2**. The new analysis of BCR-2 reported here is compared major and trace element compositions for this reference material reported in **Jochum et al. (2016)**. Whole rock major and trace element analyses of the AVON2/3-67-1, AVON2/3-66-1, AVON2/3-65-18 and ALIA-DR129-05 were made following the same methods and data are reported in **Jackson et al. (2010)**.

In situ major element analyses on glass by electron microprobe at UC Santa Barbara.

Glass was available for EX1702-D3-2. Sample chips were analyzed by electron microprobe at UC Santa Barbara using primary standards and following analytical conditions outlined in **Jackson et al. (2015)**. The MORB basaltic secondary standard 519-4-1 was analyzed repeatedly throughout the analytical session. Major element compositions for sample unknown glass and the secondary standard (and previously published data on this secondary standard from **Melson et al., 2002**) are reported in **Table S2**.

In situ trace element analyses by LA-ICP-MS at Clermont-Ferrand.

Trace element analyses on the EX1702-D3-2 glass sample were made using a laser ablation ICP-MS system housed at Laboratoire Magmas et Volcans at Clermont-Ferrand. Analytical methods are outlined in **Oulton et al. (2016)** and **Reinhart et al. (2018)**. Analyses were made using a Thermo Scientific Element XR ICP-MS coupled to a Resonetics M-50E 193 nm ArF excimer laser. ^{43}Ca was used as an internal standard. All surfaces were preablated (for 1 s at 10 Hz) prior to analysis. Analyses of samples and standards used a 47 μm laser spot, and the laser was fired with a 4 Hz repetition rate. Analyses were conducted over 80 second ablation periods, with 20 seconds of blank analysis (with the laser off) before samples analysis and (following a washout period) 20 seconds of blank analysis (again, with the laser off) after the analysis. Analyses were made in low resolution mode using triple mode with a 20% mass window and a 20 ms integration window. Acceleration voltage was scanned between magnet scans to ensure peak positions were maintained. Calibration curves were generated using NIST612 (**Gagnon et al., 2008**) and BCR-2 (**Jochum et al., 2006**) glass. Replicate analyses of a MORB glass, 519-4-1, were made throughout the analytical session to monitor precision and accuracy of analyses. The reproducibility of the trace element analyses was better than 10% (2RSD, N=8) for all elements except for Cs (44%). Measured concentrations are compared with previously published analyses from **Gale et al. (2013)** in **Table S2**.

Figure Captions

Figure S1. Isotopic data for volcanoes in this study plotted with existing data for Macdonald and Arago volcanoes. The Rose atoll, Malulu seamount, and Dino seamount are all geochemically linked to the Macdonald hotspot, consistently grouping with Macdonald-type volcanoes. The Moki seamount falls into the region where the Macdonald and Arago isotope spaces overlap in all plots except for the plot of $^{176}\text{Hf}/^{177}\text{Hf}$ versus $^{143}\text{Nd}/^{144}\text{Nd}$ where it clearly links to Macdonald. A hotspot origin for Papatua cannot be determined as it consistently plots in the region of overlap between Macdonald and Arago isotope spaces. The Moki and Malulu isotopic data produced for this study are from clinopyroxene phenocrysts, as seawater alteration prevented the analysis of whole rock samples. New data also include pillow rim glass analyses from Rose atoll, whole rock data from Dino seamount, and new whole rock data on Rose and Malulu lavas. Whole rock data for the Rose atoll and the Malulu and Papatua seamounts was published by Jackson et al., 2010. All data not produced by this study was previously published and downloaded from Georoc (<http://georoc.mpch681mainz.gwdg.de/georoc>). Figure modified after Jackson et al. (2020).

Figure S2. Age-distance relationship for Arago and Macdonald volcanoes, with projected ages for interloper volcanoes Moki, Malulu, Dino, Papatua, and the Rose atoll for both Macdonald and Arago plume origin. Hawaiian hotspot data are shown for reference. This figure uses the great circle distances between current hotspot locations and a related volcano along the Wessel and Kroenke (2008) reconstructed trends. The volcanoes in this study plot in between the CAVL Macdonald volcanoes and the Macdonald hotspot-related Tokelau islands, suggesting that they bridge a geographic gap in Macdonald-type isotope geochemistry. Ages have been estimated for the five interloper volcanoes, based on the location of each volcano on the along-track distance trends, for both a Macdonald and Arago hotspot origin. Assuming Macdonald origin for all seamounts and the Rose atoll, Moki is ~51 Ma, Papatua is ~46 Ma, Malulu is ~44 Ma, Rose atoll is ~43 Ma, and Dino is ~39 Ma. Assuming Arago

origin, Moki is ~27 Ma, Papatua is ~25 Ma, Malulu is ~23 Ma, Rose atoll is ~22 Ma, and Dino is ~21 Ma. Age data used in this plot are provided in Jackson et al. (2020). Figure modified after Jackson et al. (2020).

Figure S3. Total alkali versus SiO₂ diagram for whole rock lavas analyzed in this study. Whole rock data from other Cook-Austral volcanoes are shown for reference. The dashed line represents the boundary between the alkali (above the line) and tholeiitic (below the line) fields. The samples analyzed here plot broadly in the region defined by other volcanoes from the Cook-Austral volcanic lineament. Major elements are shown as normalized to 100% totals on a volatile-free basis. Major element data for the Malulu hyaloclastite (EX1702-12-5) are not shown, as only clinopyroxenes were analyzed.

Figure S4. Trace element spider diagrams for whole rock and clinopyroxene samples from study volcanoes. Trace element concentrations are normalized to pyrolite from McDonough and Sun (1995). Whole rocks are shown in the top panel, and clinopyroxenes in the lower panel.

1. All data in the table are reported relative to the following international standard values: Nd isotopes are corrected to JNdi value of 0.512099 (Garcon et al., 2018), Sr isotopic data to an NBS 987 value of 0.710240, Pb isotopic compositions are corrected to the NIST 981 values of Eisele et al. (2003) (16.9409, 15.4976, 36.7262), and Hf isotopic data are corrected to the JMC-475 of 0.282160. For the data from Weis et al (2006, 2007), Nd isotopic compositions are renormalized to a JNdi equivalent value of 0.512099 using Tanaka et al.'s (2000) La Jolla to JNdi-1 conversion, and their Pb isotopic data are renormalized to the NBS981 values from Eisele et al. (2003), and only teflon data are shown for the Hf isotopic dataset. Italicized data are previously published from Jackson et al (2010), and represent Sr, Nd, and unspiked Pb run by TIMS at WHOI (and are renormalized to the international standard values provided above). For the Weis et al (2006, 2007 data), errors are reported as 2SD of multiple analyses (all other errors in the table are 2SE), except for the BCR analysis at University of South Carolina (which is the 2SD of 5 analyses of the same BCR-2).

2. All leaching, wet chemistry (sample dissolutions and chemical separations) and mass spectrometry (all using MC-ICP-MS) for Sr, Nd, Pb and Hf isotopes completed at U. South Carolina.

3. Leaching and wet chemistry (sample dissolutions and chemical separations) for Sr, Nd, and Pb completed at UCSB. Sr and Nd mass spectrometry completed on UCSB TIMS, and Pb mass spectrometry (if any) completed on U. South Carolina MC-ICP-MS.

4. Leaching and wet chemistry (sample dissolutions and chemical separations) for Sr, Nd, and Pb completed at UCSB. Sr and Nd mass spectrometry completed on UCSB TIMS, and Pb mass spectrometry (if any) completed on WHOI MC-ICP-MS.

5. Leaching and wet chemistry (sample dissolutions and chemical separations) and mass spectrometry for Sr, Nd, and Pb completed on WHOI TIMS (data published in Jackson et al., 2010).

6. Leaching and wet chemistry (sample dissolutions and chemical separations) and mass spectrometry for Sr, Nd, and Pb completed on WHOI MC-ICP-MS (data published in Jackson et al., 2010).

7. This result is superseded by new analyses of this sample made at UCSB (also presented in this table).

Table S2. Major and trace element concentrations lavas published in this study together with prior analyses of related seamounts.

1. For whole rock samples EX1702-D7-2, EX1702-D11-1, and EX1702-D3-2, major elements and a subset of trace elements analyzed by XRF, and some of these trace elements and an additional set of trace elements were analyzed by solution ICP-MS. A BCR-2 reference material was analyzed as an unknown together with the samples in this study and previously published data on the BCR-2 are reported in [Jochum et al. \(2016\)](#) and shown in this table for reference.

2. Trace elements and a subset of major elements on clinopyroxene separates (EX1702-D7-2 and EX1702-D12-5) were run by solution ICP-MS at the University of South Carolina. Published major and trace element concentrations for this reference materials are from [Jochum et al. \(2016\)](#) and are shown in this table for reference; the major element concentrations from [Jochum et al. \(2016\)](#) are here normalized to 100% total with all Fe reported as FeO.

3. Italicized data were previously published in [Jackson et al. \(2010\)](#), and include two lavas from Rose atoll, 1 lava from Papataua seamount, and 1 lava from Malulu seamount. LOI's (Loss On Ignition) are estimated for these 4 lavas after [Jackson et al. \(2010\)](#).

4. The major element composition of the EX1702-D3-2 glass is the average of three different spot analyses by electron probe. The major element composition of the ALV-519-4-1 reference glass is the average of 22 different spot analyses analyzed during the same analytical session as EX1702-D3-2, and the data are shown together with published of ALV-519-2 values from [Melson et al. \(2002\)](#). The trace element composition of the EX1702-D3-2 glass is the average of four different spot analyses by LA-ICP-MS. The trace element composition of the ALV-519-4-1 reference glass is the average of 8 different spot analyses during the same analytical session as EX1702-D3-2, and the data are shown together with published data on ALV-519-4-1 from [Gale et al. \(2013\)](#) and compiled in [Jackson et al. \(2015\)](#).
