Abstract

The adolescent idiopathic scoliosis (AIS) is a 3D deformity of the spine whose origin is unknown and clinical evolution unpredictable. In this work, a mixed theoretical and numerical approach based on energetic considerations is proposed to study the global spine deformations. The introduced mechanical model aims at overcoming the limitations of computational cost and high variability in physical parameters. The model is constituted of rigid vertebral bodies associated with 3D effec-tive stiffness tensors. The spine equilibrium is found using minimization methods of the mechanical total energy which circumvents forces and loading calculation. The values of the model parameters exhibited in the stiffness tensor are retrieved using a combination of clinical images post-processing and inverse algorithms implementation. Energy distribution patterns can then be evaluated at the global spine scale to investigate given time patient-specific features. To verify the reliability of the numerical methods, a simplified model of spine was implemented. The methodology was then applied to a clinical case of AIS (13-year-old girl, Lenke 1A). Comparisons of the numerical spine geometry with clinical data equilibria showed numerical calculations were performed with great accuracy. The patient follow-up allowed us to highlight the energetic role of the apical and junctional zones of the deformed spine, the repercussion of sagittal bending in sacro-illiac junctions and the significant role of torsion with scoliosis aggravation. Tangible comparisons of output measures with clinical pathology knowledge provided a reliable basis for further use of those numerical developments in AIS classification, scoliosis evolution prediction and potentially surgical planning.

1 Introduction

The adolescent idiopathic scoliosis (AIS) is a multifacto-rial disease potentially involving genetic, metabolic and mechanical aspects, and which affects up to 3% of the 10--16 years population with a significant female prevalence. AIS is characterized by the deviation of anatomical spine cur-vature toward coupled 3D deformation involving abnormal bending and torsion. It generally shows a rapid evolution during the growth spurt (Riseborough and Wynne-Davies 1973) which can lead to respiratory and cardiac disorders.

If orthotic treatment fails to stop progression which happens in 10% of AIS, the surgery is indicated. Scoliosis clinical management might improve the early diagnosis, the predic-tion of its unstable evolution and deterministic information for the surgical planning.

The proposed methodology concerned a mechanical approach to explore the equilibrium of adolescent scoliotic spines. The causality of the disease is not studied. In the literature, several modeling strategies have been proposed to predict the mechanical response of a scoliotic spine. In van der Plaats et al. (2007), the authors developed a numerical finite element model to test a buckling hypothesis as initia-tion of the AIS. The results were descriptive and comparison with clinical data remained to be performed. Lafage et al. (2004) investigated an all spine model using adapted struc-tural elements, but as pointed out by the authors, no physical model was developed to adjust the mechanical parameters used. Drevelle et al. (2010) proposed a 3D FEM model to

mimick AIS evolution, a study that was limited by the lack of follow-up to assess the clinical evolution of the spine. Despite significant progress in the anatomy characterization of AIS (Araújo et al. 2017) and previously cited modeling efforts, most of studies resulted in qualitative propositions for scoliosis description.

In particular, the 3D generic approach of FEM finds its limitation in the size of the problem and the lack of knowledge in tissue properties and boundary conditions in vivo (Ferguson et al. 2004; Jebaseelan et al. 2012). Alternative discrete mechanical models of children spines involving soft tissues and muscles have been proposed (Schmid et al. 2019). To examine the soft tissues and, especially the intervertebral disk (IVD) role into the AIS time course, studies at reduced scale have been proposed. For instance, Stokes (2007) focused on the biomechanical interaction between the IVD and the vertebral body in scoliosis evolution. This hypothesis is supported by recent clinical studies which highlight the altered response of disk in AIS population (Abelin-Genevois et al. 2015; Langlais et al. 2018). The poromechanical response of vertebral segments was numerically predicted using a dedicated substructuring technique to reduce computation costs (Swider et al. 2010). As soft tissues are structures with maximal energy gradients (Violas et al. 2007; Noailly et al. 2007; Swider et al. 2010), multiple studies focused more specifically on the IVD characterization. Information about effective mechanical properties of IVD (Newell et al. 2017) and some components of segment effective stiffness are available (Schultz et al. 1979; Stokes et al. 2002; Meng et al. 2015). However, these approaches involved ex vivo experimental measurements and none of them concerned the adolescent. Another strategy could be to identify in vivo properties at tissue scale (Jebaseelan et al. 2012; Langlais et al. 2018; O'Connell et al. 2007) but pediatric functional imaging are rarely available.

To address the lack of physical parameters availability and the numerical limitations, we aimed at developing a new mechanical and numerical model in order to characterize the overall scoliotic spine deformation. The progression of scoliosis is targeted after diagnosis and the cause of scoliosis initiation is not explored in this study. A 3D wired model that overcomes the previous limitations based on original key points was constructed. To achieve this modeling, it was hypothesized that the quasi-static evolution of scoliosis followed an energetic minimization law, and that an effective stiffness tensor which models deformable structure interacting at a vertebral segment scale existed. The values of this tensor were reconstructed based on clinical data using reverse analysis.

2 Materials and methods

In this section, we develop the wireframe model and detail the theoretical formulation based on energy minimization and numerical methods. This methodology is evaluated on a test case and applied to a clinical application on a 2 years follow-up of a 13-year-old scoliotic patient.

2.1 Parameterization of the vertebral segment

Parameterization of the spine is described in Fig. 1a, b associated with EOS® exams used in the clinical application of paragraph 2.4.2. Vertebral bodies follow rigid body motions and by contrast, disks, vertebral endplates, facet joints, ligaments and other soft tissues connected with the vertebral segments are considered as deformable tissues. Figure 1c shows a model of vertebral segment S_i including the deformable structure between two rigid vertebral bodies, V_i and V_{i+1}.

To establish the kinematic description of the wireframe model, a unique orthonormal basis $\mathcal{B}_i$ was associated to each vertebra i as shown in Fig. 1d. The vector $\mathbf{e}_{\mathbf{x}_i}$ joined the centers O_i and O'_i of vertebral endplates of the vertebra i. The second vector $\mathbf{e}_{\mathbf{y}_i}$ was defined by the orientation of the spinous process. The vector $\mathbf{e}_{\mathbf{z}_i}$ warranted the condition of a direct orthonormal reference frame. A similar method defined $\mathcal{B}_{i+1}$ attached to $i + 1$.

Considering now a vertebral segment, composed of two vertebrae (i and $i + 1$) and an IVD, the two reference frames of vertebra i were $\mathcal{R}_i(O_i, \mathcal{B}_i)$ and $\mathcal{R}_{i'}(O_{i'}, \mathcal{B}_i)$, and the ones of the vertebra $i + 1$ were $\mathcal{R}_{i+1}(O_{i+1}, \mathcal{B}_{i+1})$ and $\mathcal{R}_{i'+1}(O_{i'+1}, \mathcal{B}_{i+1})$.

The displacement continuity at the boundary of a vertebra and an IVD ensured the uniqueness of the points O_i, O'_i and led to the following linking equations for the local reference frames:

$$\mathbf{O}'_i - \mathbf{O}_i = \mathbf{L}_i, \quad \mathbf{O}_{i+1} - \mathbf{O}'_i = \mathbf{T}_i, \quad \text{and}$$
$$\mathcal{B}_{i+1} = \mathbf{R}_i \mathcal{B}_i, \tag{1}$$

where $\mathbf{R}_i$ was a rotation matrix, expressing the orientation of a base $\mathcal{B}_{i+1}$ in $\mathcal{B}_i$, and $\mathbf{O}_i$, $\mathbf{O}'_i$, $\mathbf{O}_{i+1}$ were the vector formed with the points O_i, O'_i, O_{i+1} and the point O_0. Vector $\mathbf{T}_i$ depended on the deformation of the IVD and $\mathbf{L}_{i/\mathcal{R}_i} = (l_{vi}, 0, 0)^\mathsf{T}$, l_{vi} being the length of a vertebrae.

We considered that the matrix $\mathbf{R}_i$ was the result of 3 successive rotations of 3 angles noted $\theta_i, \alpha_i, \varphi_i$ (details in "Appendix 1").

The kinematics of the vertebral body $i + 1$ was described, relative to i, in the reference frame $\mathcal{R}_i$ by the position vector $\mathbf{u}_{i/\mathcal{R}_i}$ involving the 6 components introduced in $\mathbf{T}_{i/\mathcal{R}_i}$ and $\mathbf{R}_i$:

$$\mathbf{u}_{i/\mathcal{R}_i} = (T_{xi}, T_{yi}, T_{zi}, \theta_i, \alpha_i, \varphi_i)^\mathsf{T}. \tag{2}$$

Fig. 1 EOS® radiography of a female adolescent with progressive scoliosis and parameterization of the biomechanical wireframe model. **a** Frontal acquisition at age 13 (1A Lenke type and 40° Cobb angle) and anatomical description of the spine, **b** frontal acquisition at age 15 (65° Cobb angle), **c** schematic view and notations of a vertebral segment T9–T10, only frontal components are represented and vertical gravity is **g**, **d** representation of a local reference frame associated with a vertebral body i
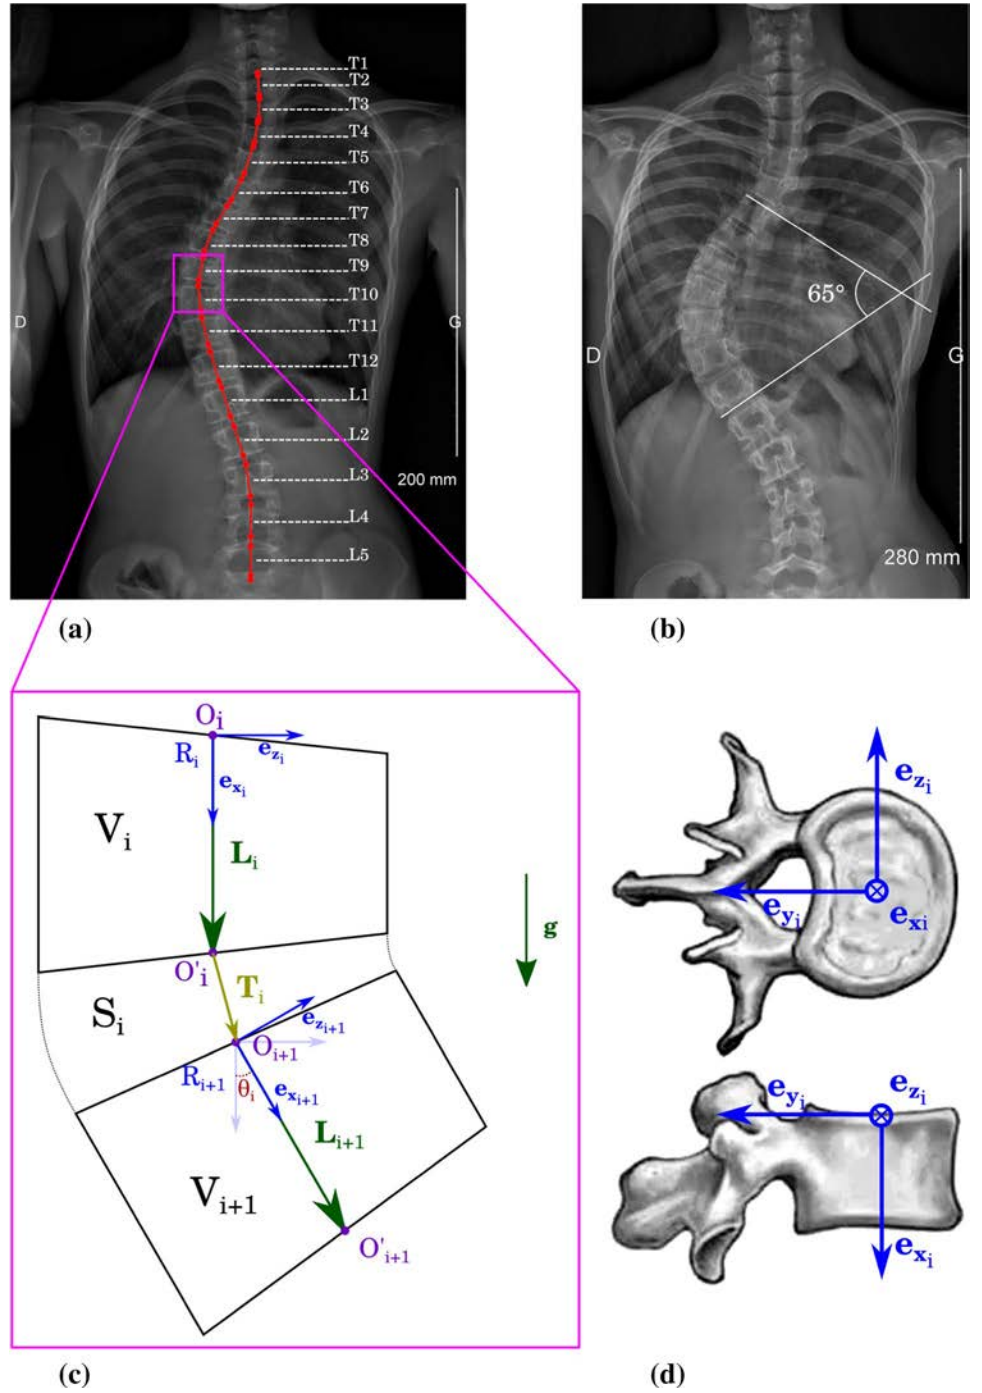

The concatenation of vectors $\mathbf{u}_{i/\mathcal{R}_i}$, noted $\mathbf{u}_{/\mathcal{R}_i}$ allowed the kinematics of the whole spine to be obtained iteratively.

To ease further developments and, especially management of spine boundary conditions and gravity loading (Sect. 2.2), the kinematic fields were also written into an absolute reference frame $\mathcal{R}_A(O_A, \mathcal{B}_A)$. The unique orthonormal basis $\mathcal{B}_A$ defined the frontal plane of the trunk in anatomical position, with O_A located at the top of the first

thoracic vertebra (T1). The basis $\mathcal{B}_i$ of each vertebra was related to the global basis $\mathcal{B}_A$ by:

$$\mathcal{B}_i = \prod_{k=1}^{i} \mathbf{R}_k \mathcal{B}_A = \mathbf{P}_i \mathcal{B}_A, \quad \text{with} \quad \mathbf{P}_i = \prod_{k=1}^{i} \mathbf{R}_k. \tag{3}$$

In Eq. (3), $\mathbf{P}_i$ was a unique rotation matrix resulting from cumulative rotations of subjacent vertebral bodies $k = 1 \ldots i$.

We had, in the global base $\mathcal{B}_A$, the expression of the vector $\mathbf{L}_i$:

$$\mathbf{L}_{i/\mathcal{R}_A} = l_{v_i} \mathbf{P}_i \cdot \mathbf{e}_{\mathbf{x}i}. \tag{4}$$

We called $\mathbf{X}_{i/\mathcal{R}_A}$ the vector characterizing the displacement of the IVD such that:

$$\mathbf{X}_{i/\mathcal{R}_A} = \mathbf{T}_{i/\mathcal{R}_A} = \mathbf{P}_i \cdot \mathbf{T}_{i/\mathcal{R}_i}. \tag{5}$$

However, the position of the points O_i, $O_{i'}$ allowed us to only know the location of each vertebral body. To keep track of the information concerning the orientation of the vertebrae (torsion), we also introduced $\mathbf{Y}_{i/\mathcal{R}_A}$:

$$\mathbf{Y}_{i/\mathcal{R}_A} = \mathbf{P}_i \cdot \mathbf{e}_{\mathbf{y}i} \tag{6}$$

For further use, we called $\mathbf{u}_{/\mathcal{R}_A}$ the concatenation of the vectors $\mathbf{X}_{i/\mathcal{R}_A}$ and $\mathbf{Y}_{i/\mathcal{R}_A}$.

2.2 Governing equations of spine balance by minimization of total potential energy

The spine dynamics was studied in a time scale long enough to smooth daily variations and short enough to assume a closed and non dissipative system. Consequently, transient effects due to diffusion, convection, and structural damping could be averaged in the studied time window τ during which all forces could be considered conservative. The model achieves an extraction of mechanical parameters from clinical data at the specific time of the X-ray image capture. No growth model has been integrated. For each different clinical data, i.e., time point, a new numerization is performed from which we can deduce the length of the vertebrae and of the IVD, although the IVD growth is very limited for the patient studied as she is older than 12. The first hypothesis was that the spine mechanical behavior could be described by a succession of quasi-static states, at equilibrium in τ. The second hypothesis was that the nonlinear mechanical response eventually due to nonlinear material properties, large displacements or large strains, could be searched in the form of successive piecewise linear equilibria. This implied that associated forces derived from a local potential.

The total potential energy V was the sum of internal strain energy of the isolated segment generated by the strain of the deformable structure between one vertebra relatively to the adjacent one and the work of external loading taking into account the distributed body weight (gravity) and the role of muscles and ligaments. Components of vector $\mathbf{u}$ were nondimensionalized by the height of thoracic and lumbar spine of the patient.

The segment displacement field $\mathbf{q}_i$ was defined by the difference between the kinematics $\mathbf{u}_i$ and a reference energy state $\mathbf{u}_i^0$. The independent symmetric tensors $\mathbf{K}_i$ (6×6) and $\mathbf{B}_i$ (6×6) were, respectively, associated with local strain energy and potential energy of external mechanical forces. Therefore, the contribution of forces inside the vertebral segment and due to disk, muscles or any other tissue was included into the effective tensor $\mathbf{K}$. The contribution of forces outside the vertebral segment such as dorsal muscle, gravity, or other components such as braces, was included into the effective tensor $\mathbf{B}$. Vector $\mathbf{G}_i$ (1×6) represented the contribution of gravity forces. In the following, the variable $\mathbf{p}$ will correspond to the components of the effective tensors ($\mathbf{K}$ and $\mathbf{B}$) and to the reference state $\mathbf{u}^0$. The dependence of the total potential energy V to $\mathbf{u}$ and $\mathbf{p}$ was defined as:

$$\begin{aligned} V(\mathbf{u}, \mathbf{p}) = &\sum_i \mathbf{q}_i^\top \cdot \mathbf{K}_i \cdot \mathbf{q}_i + \\ &\sum_i \mathbf{q}_i^\top \cdot \mathbf{B}_i \cdot \mathbf{q}_i - \\ &\sum_i \mathbf{G}_i \cdot \mathbf{q}_i. \end{aligned} \tag{7}$$

When considering energy from internal deformation of a vertebral segment, the displacement was expressed in local coordinates, with a relative unconstrained position of one vertebra to the adjacent one [Eq. (8)]. When considering the work of external forces, the description of the spine was developed in the absolute reference frame [Eq. (9)].

$$\mathbf{q}_{i/\mathcal{R}_i} = \mathbf{u}_{i/\mathcal{R}_i} - \mathbf{u}_{i/\mathcal{R}_i}^0, \tag{8}$$

$$\mathbf{q}_{i/\mathcal{R}_A} = \mathbf{u}_{i/\mathcal{R}_A} - \mathbf{u}_{i/\mathcal{R}_A}^0. \tag{9}$$

Using Eqs. (8) and (9), Eq. (7) became:

$$\begin{aligned} V(\mathbf{u}, \mathbf{p}) = &\sum_i \mathbf{q}_{i/\mathcal{R}_i}^\top \cdot \mathbf{K}_i \cdot \mathbf{q}_{i/\mathcal{R}_i} + \\ &\sum_i \mathbf{q}_{i/\mathcal{R}_A}^\top \cdot \mathbf{B}_i \cdot \mathbf{q}_{i/\mathcal{R}_A} - \\ &\sum_i \mathbf{G}_i \cdot \mathbf{q}_{i/\mathcal{R}_A}. \end{aligned} \tag{10}$$

Kinematics boundary conditions were imposed at the limits of the region of interest. Locations and orientations of extremal vertebral bodies were obtained from X-ray clinical exams and used as input into the absolute reference frame.

2.3 Numerical resolution

2.3.1 Resolution of the direct problem

Knowing a set of parameters $\mathbf{p}$, the admissible stationary kinematic field $\mathbf{u}$ which minimized V was called $\mathbf{u}_{eq}(\mathbf{p})$ and described the static equilibrium of the system. The stability conditions were described as:

$$\mathbf{u}_{\text{eq}}(\mathbf{p}) = \underset{\mathbf{u}}{\text{argmin}}(V(\mathbf{u}, \mathbf{p})). \tag{11}$$

The problem of minimum search was strongly nonlinear, and the surface response of the function $V(., \mathbf{p}) : u \mapsto V(\mathbf{u}, \mathbf{p})$ was non convex. Solutions were found by implementing a trust-region algorithm and a Newton algorithm [Scipy library, Virtanen et al. (2019)] sequentially to accelerate convergence. Gradient $\nabla_{\mathbf{u}} V$ and hessian matrix $\nabla_{\mathbf{u}} \nabla_{\mathbf{u}} V$ were also analytically calculated to minimize computation time.

2.3.2 Resolution of the inverse problem

For the clinical problem, we did not have access to mechanical tensors nor initial reference states. To identify the parameters and to test the robustness of our approach, we implemented an inverse problem methodology (Tarantola 2005). This was formulated by the set of Eqs. (12), (13) and (14) where $\mathbf{u}_{\text{eq}}(\mathbf{p})$ was the kinematic equilibrium, $\mathbf{u}_{\text{c}}$ was the observed clinical equilibrium (EOS® X-ray) and $\mathbf{p}_{\text{sol}}$ was the converged solution of mechanical parameters:

$$\begin{aligned} \mathbf{p}_{\text{sol}} &= \underset{\mathbf{p}}{\text{argmin}} \left(f(\mathbf{u}_{\text{eq}}(\mathbf{p}), \mathbf{p}) \right) \\ &\text{with} \quad f(\mathbf{u}_{\text{eq}}(\mathbf{p}), \mathbf{p}) = d(\mathbf{u}_{\text{eq}}(\mathbf{p})) + c(\mathbf{p}), \end{aligned} \tag{12}$$

$$d(\mathbf{u}_{\text{eq}}(\mathbf{p})) = (\mathbf{u}_{\text{eq}}(\mathbf{p}) - \mathbf{u}_{\text{c}})^{\mathsf{T}} \cdot \mathbf{S} \cdot (\mathbf{u}_{\text{eq}}(\mathbf{p}) - \mathbf{u}_{\text{c}}), \tag{13}$$

$$\begin{aligned} c(\mathbf{p}) = \, &\epsilon_1 \sum_{k=1}^{6} (\bar{K}_{k,k} - K_{\text{prior}_{k,k}})^2 + \\ &\epsilon_2 \sum_{k=1}^{6} \sum_{i=1}^{m} (K_{k,k,i} - \bar{K}_{k,k})^2 + \\ &\epsilon_3 (\|\mathbf{u}^0 - \mathbf{u}_{\text{prior}}^0\|^2), \end{aligned} \tag{14}$$

with $\bar{K}_{k,k}$ the mean value defined as: $\bar{K}_{k,k} = \frac{1}{m} \sum_i K_{k,k,i}$ and m the number of vertebral segment. The formulation was adapted to full effective tensors $\mathbf{K}$ and $\mathbf{B}$. The problem size was reduced when clinical applications were considered and only diagonal terms of stiffness tensor $\mathbf{K}$ were taken into account. Therefore, only those terms appeared in the penalty function $c(\mathbf{p})$ described by Eq. (14).

The objective function f involved the distance function d and the penalty function c. The distance function weighted the norm of discrepancies between predicted equilibrium $\mathbf{u}_{\text{eq}}(\mathbf{p})$ and clinical data $\mathbf{u}_{\text{c}}$. The direct problem resolution provided $\mathbf{u}_{\text{eq}}(\mathbf{p})$ at each incremental step. Matrix $\mathbf{S}$ was used to attenuate the impact of values with smaller precision from the clinical data (rotation of vertebrae). Penalty function $c(\mathbf{p})$ aimed at deforming the image surface of the objective function f in order to give more weight to the set of parameters minimizing the penalty function c. Mean values and

variances of tensors coefficients were, respectively, penalized in first term and second term of equation (14) using prior values as controls.

The inverse problem was solved using a Newton conjugate gradient algorithm (Scipy library) which required the first and second derivatives of the objective function f. The first derivation was obtained using the adjoint method detailed in "Appendix 2". The second derivation was evaluated numerically using finite differences, exploiting the multi-core potential of the computer to fill the hessian matrix $\nabla_{\mathbf{p}} \nabla_{\mathbf{p}} f$ faster (linear acceleration).

The nondimensionalized difference a_{ec} of $\mathbf{u}_{\text{eq}}$ and $\mathbf{u}_{\text{c}}$ expressed by Eq. (15) was an indicator of the methodology accuracy with a 0 value for a perfect fit.

$$a_{\text{ec}} = \frac{\|\mathbf{u}_{\text{eq}} - \mathbf{u}_{\text{c}}\|}{\|\mathbf{u}_{\text{c}}\|} \tag{15}$$

Beyond the determination of the kinematic field, the methodology allowed us to determine the distribution patterns of energies using Eq. (7). The model proposed an energy method to circumvent the ignorance of forces, tissue properties, detailed anatomy and local boundary conditions, by assuming the existence of energy local potentials. As a result, distribution patterns of energies were determined using Eq. (10). In addition, forces considered as model output measures, could be calculated using Eq. (16) in post-processing thanks to equilibrium $\mathbf{u}_{\text{eq}}$ and effective parameters $\mathbf{p}$ obtained from the inverse problem.

$$\mathbf{F}_i = \mathbf{K}_i \mathbf{q}_{i/\mathcal{R}_i} + \mathbf{B}_i \cdot \mathbf{q}_{i/\mathcal{R}_A} + \mathbf{G}_i \tag{16}$$

However, we will not work with forces distribution in the spine in the following and only the energetic approach will be exploited as it includes more information, it circumvents the lack of loading knowledge at the boundary conditions and it is the starting point of our model.

2.4 Applications

2.4.1 Numerical test case of a 34 elements simplified spine

The vertical wireframe model was made of 34 elements corresponding to $m = 17$ vertebral bodies and deformable elements as shown in Fig. 2a. Diagonal terms of $\mathbf{K}$ were fixed to 1 and all other components were nil. The reference state was defined by $\mathbf{u}_{i/\mathcal{R}_i}^0 = (1, 0, 0, 0, 0, 0)^{\mathsf{T}}$, $i = 1.17$ in the local reference frames. This set of parameters was called $\mathbf{p}_{\text{ref}}$ in the following parts. Boundary conditions in the absolute reference frame were $\mathbf{u}_{/\mathcal{R}_A}(1) = (0, 0, 0, 0, 0, 0)^{\mathsf{T}}$ and $\mathbf{u}_{/\mathcal{R}_A}(17) = (25, 0, 0, 0, 0, 0)^{\mathsf{T}}$.

We solved the direct problem and verified its convergence. We ran it multiple times to obtain many possible

Fig. 2 Numerical test case with 34 wireframe elements mimicking a simplified adolescent spine: **a** wireframe schematic view, **b** four solutions $\mathbf{u}_{eq}$ of the direct problem, **c** convergence of the inverse problem in term of objective function and residual
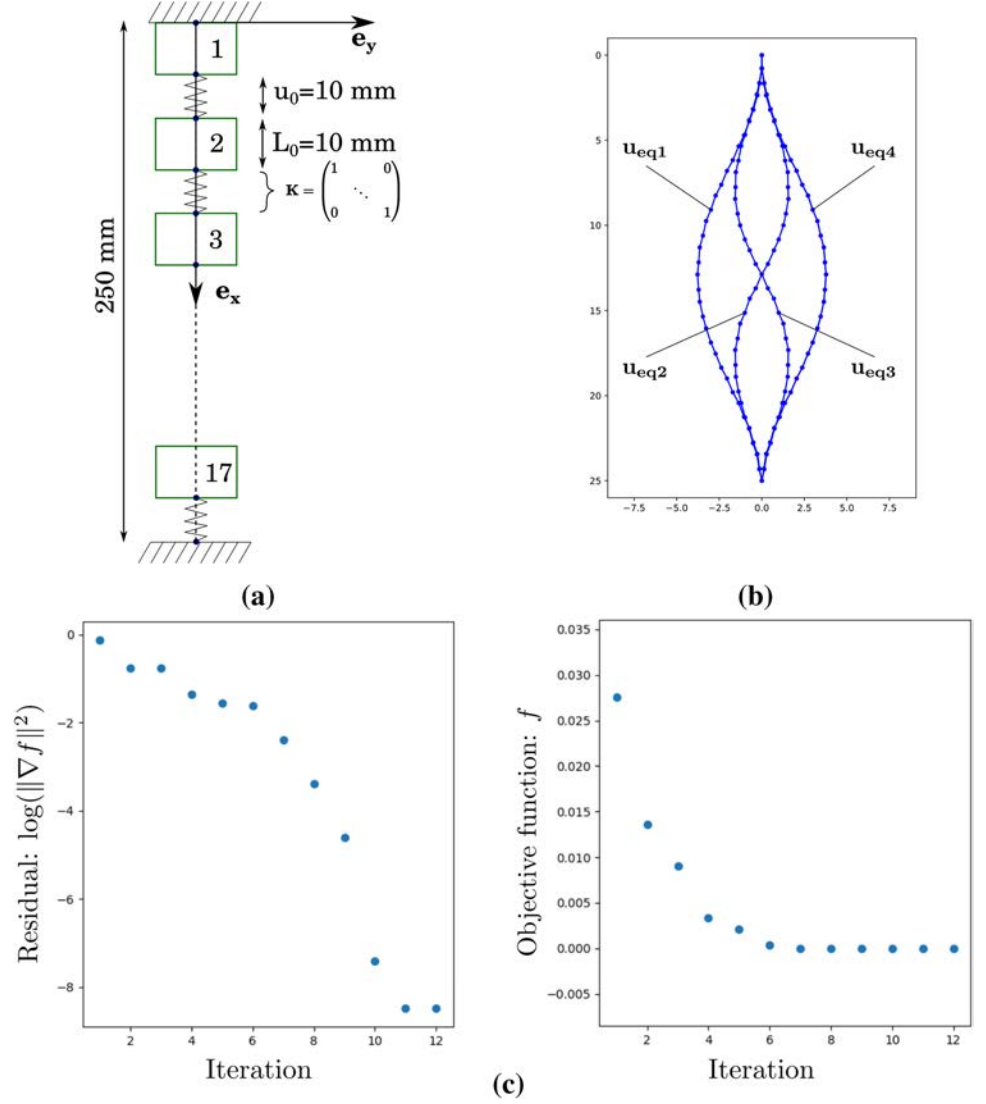

equilibrium positions. We then chose one of the equilibrium position, and used it as reference position $\mathbf{u}_c$ for the test on the inverse problem. We solved the inverse problem using this reference geometry and verified the convergence of the numerical solver first. Then we verified that the solution geometry $\mathbf{u}_{eq}$ and $\mathbf{u}_c$ were the same. Ultimately, we looked for a correspondence between the solution parameters and the reference ones.

2.4.2 Clinical application

Clinical data were extracted from a clinic radiological prospective monocentric study approved by the Institutional Review Board of the Ethic Committee (Toulouse University Hospital). Spine geometry in frontal and sagittal planes were obtained in vertical position by a low-dose X-ray EOS® system. The rotation of vertebrae was calculated using the remoteness of the spinal process. The selected patient was a 13-year-old girl diagnosed with a 1A scoliosis according to Lenke classification (Lenke et al. 2001) and a 40° Cobb angle in 2014. The deformation progressed to 65° and ended up to a T2–L2 surgical spinal fusion in 2016 (Fig. 1b for an illustration of Cobb angle).

A python® custom-made script was implemented in ImageJ® to build the wireframe description of the scoliotic spine from T1 to L5 and to build $\mathbf{u}_c$ for 34 elements. The boundary conditions were fixed in term of location and orientation in T1 and L5. The reference state was defined assuming an isotropic level dependent compression of deformable elements in standing position, i.e $\mathbf{u}_0 = \alpha \times \mathbf{u}_c$. This approximation of $\mathbf{u}_0$ was based on the mean size variation of healthy patient between morning and night (Ludescher et al. 2008; Zhu et al. 2015).

The terms of effective mechanical tensors $\mathbf{K}_i$ and $\mathbf{B}_i$ were reduced to the diagonal terms and associated priors of Eq. (12) were adapted from the literature (Meng et al. 2015;

Newell et al. 2017). The gravity loading $\mathbf{G}_i$, followed the values introduced in Villemure et al. (2004). These choices still led to an inverse algorithm dealing with a size of 153 parameters. In this clinical application, the direct problem numerical resolution was starting close to $\mathbf{u}_c$ contrary to the simplified spine model in Sect. 2.4.1 which explored the multiplicity of solutions. This methodology, in addition to asymmetric boundary conditions, lead to the uniqueness of equilibrium geometry $\mathbf{u}_{eq}$.

A sensitivity study has been performed to evaluate the impact of errors on parameter calculations. Its main aspects are described in "Appendix 3".

3 Results

3.1 Numerical test case of a 34 elements simplified spine

The direct problem was geometrically under-constrained and several admissible equilibria for $\mathbf{u}_{eq}$ have been obtained from energy minimization. Four solutions or deformation modes, $\mathbf{u}_{eq1}$, $\mathbf{u}_{eq2}$, $\mathbf{u}_{eq3}$, $\mathbf{u}_{eq4}$, have been selected in Fig. 2b. The convergence criterion of energy balance minimization was lower than 10^{-12}. Calculations lasted between 0.2 s and 1 min CPU time on a desk computer (Intel Xeon® 3.6GHz). The inverse problem algorithm was applied using $\mathbf{u}_{eq1}$ as the targeted kinematic mode. It also played the role of $\mathbf{u}_c$ previously introduced in paragraph 2.3.2. The initial vector of effective properties $\mathbf{p}$, i.e., $\mathbf{K}_i$, $\mathbf{B}_i$ and $\mathbf{u}_i^0$, was randomly generated with values between $0.5 \times \mathbf{p}_{ref}$ and $1.5 \times \mathbf{p}_{ref}$.

Without using the penalty function $c(\mathbf{p})$, the converged solution $\mathbf{p}_{sol}$ slightly differed from the target $\mathbf{p}_{ref}$ as shown in Fig. 3. However, the converged solution geometry $\mathbf{u}_{eq1}$ was perfect with $a_{ec} \simeq 0$. When $c(\mathbf{p})$ was used with priors corresponding with $\mathbf{p}_{ref}$, then both kinematic balance $\mathbf{u}_{eq1}$

and effective properties $\mathbf{p}_{sol}$ were predicted with $a_{ec} \simeq 0$ and the energy distribution fitted the reference energy (Fig. 3). A good convergence was obtained, as shown in Fig. 2c with computation times lower than 1 h CPU time.

3.2 Clinical application

For the clinical application, the fitting of spine balance $\mathbf{u}_{eq}$ on clinical data $\mathbf{u}_c$ was excellent since a_{ec} was lower than 3×10^{-3} (Fig. 4a–c). As shown in Fig. 4d the convergence of the inverse problem was obtained for calculations lasting between 2 and 8 h (CPU time) with a convergence criterion lower than 10^{-8}. When the impact of distance function d and regularization function c (identical in 2014 and 2016) was examined, it was found that $d(\mathbf{p}_{sol})$ was always lower than one third of $c(\mathbf{p}_{sol})$. It showed that the penalty function was properly chosen and did not altered the main purpose of the algorithm to fit clinical and modeled geometries.

Table 1 summarizes the contribution of energy components, i.e., compression, lateral bending, sagittal bending and torsion, to the total energy of the spine. Components were calculated into the segment local reference frame. In 2014, bending energy was predominant and that of lateral bending in the frontal plane greater than that in the sagittal plane. The compression energy and torsion energy were found with a smaller percentage. The evolution in 2016 did not modify the prominence of bending but compressive energy decreased to the benefit of lateral and torsion energy.

The distribution patterns of energies along the spine are plotted in Fig. 5. Figure 5a shows an oscillation of the lateral bending, especially marked in the apical zone (vertebral segment S8, S9, S10, corresponding to vertebrae T8–T11) in 2014. For the evolving scoliosis in 2016, the energy peak strongly emerged and a noticeable increase was predicted in the lower junctional zone (S14, corresponding to vertebrae L2–L3). The sagittal energy in

EOS® exam date	Compressive	Flexion extension	Lateral bending	Torsion
2014	18	52	19	10
2016	10	54	25	12

Fig. 5b showed an almost steady distribution up to the junctional zone (S13, corresponding to L1–L2) followed by a monotonic increase reaching its maximum value at the sacro-illiac junction (S17, corresponding to L5-Sacrum). Scoliotic deformation exacerbated energy concentration in 2016. Concerning torsion energy Fig. 5c, the distribution was disrupted by a sudden increase before the apex (S5–S6, corresponding to T5–T7) and particularly marked in 2016. Maximum values were reached in the upper junctional zone (S6, corresponding to T6–T7). It was also observed that the lower junctional zone (S12, S13, corresponding to T12–L2) showed a noticeable increase of torsion energy in 2016.
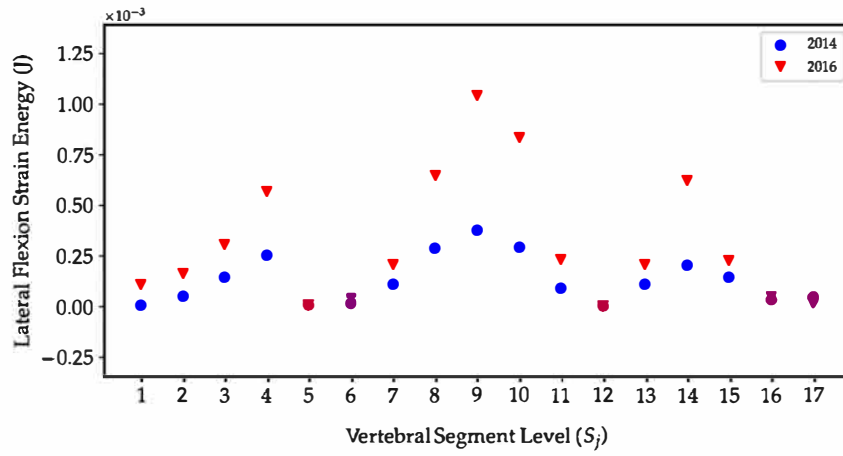

Fig. 5 Clinical application: 2 years follow-up of a 13-year-old girl (1A Lenke type, 40° Cobb angle in 2014, 65° Cobb angle in 2016). Energy distribution patterns: **a** lateral bending (frontal plane), **b** flexion-extension (sagittal plane), **c** torsion

4 Discussion

We initially hypothesized that a wireframe model based upon mechanical energy minimization might depict the spine balance in scoliosis time course. The governing equations and the associated numerical direct and inverse methods were first evaluated with a test case mimicking a simplified spine architecture, and second with a 2 years evolving scoliosis. The nonlinear response was searched in the form of successive piece-wise linear equilibria and in the vicinity of the equilibrium all forces derived from a local potential. Progressive results supported the proposed methodology and confirmed our central hypothesis.

We proposed the concept of mechanical effective tensor to condense, in a reduced number of scalars, the complex behavior of spine segments involving bones and soft tissues. Additionally, patient medical images constrained the inverse algorithm to check kinematic and mechanical balances to warrant the clinical relevance of the methodology. The penalization process guided the inverse problem resolution among multiple numerical admissible solutions.

Despite the concept of effective tensors, the amount of unknowns was still diminished to diagonal components because they played major roles. While accelerating numerical resolution, this choice provided convincing results compared to clinical diagnosis. However, the set of equations can predict the influence of coupled mechanical loading (i.e bending, torsion, compression) with enhanced clinical relevance by exploring the impact of extra diagonal terms potentially asymmetric. Especially, this could improve predicting the structure nonlinear response due to loading history.

The time scale of the clinical follow-up, allowed us to assume that the AIS evolution could be considered as being a steady-state mechanical problem at each time observation. Two snapshots at 2 year intervals were selected to establish the clinical relevance of our proposed methodology. The domain was restrained to thoracic and lumbar segments. Indeed, cervical spine balance is rarely deformed by AIS and it is mainly determined by the dynamical maintain of horizontal sight.

AIS deformation was interpreted in terms of mechanical energies and this objective quantification allowed completing the empirical clinical approach. As observed clinically, we found that the apical zone was playing a significant role in energy concentration, especially for lateral bending and torsion. Beyond that, the prominence of sagittal bending found in sacro-illiac junction was also corroborated by previous clinical studies (Brink et al. 2018). The junction zones located on both sides of the apex observed in clinics by curve inversion showed intrinsic variations of energies and notably for torsion. Indeed, these zones are examined to establish clinical diagnosis, AIS classification and surgical planning.

In this article, the energy distribution obtained from available clinical data was calculated. This can be considered as the basis of further clinical studies on multicentric cohorts involving main types of AIS in Lenke classification and the concept of stable or unstable scoliosis. The implementation of specific algorithms will allow a prediction of scoliotic curve progression by the analysis of segments effective properties. In that case, the clinically enriched models will be considered as being predictive models.

Appendix 1: Rotation matrix

Rotation matrix R_i:

$$\begin{pmatrix} \cos\theta_i\cos\alpha_i & -\sin\theta_i\cos\alpha_i & \sin\alpha_i \\ \sin\theta_i\cos\varphi_i + \cos\theta_i\sin\alpha_i\sin\varphi_i & \cos\theta_i\cos\varphi_i - \sin\theta_i\sin\alpha_i\sin\varphi_i & -\cos\alpha_i\sin\varphi_i \\ \sin\theta_i\sin\varphi_i - \cos\theta_i\sin\alpha_i\cos\varphi_i & \cos\theta_i\sin\varphi_i + \sin\theta_i\sin\alpha_i\cos\varphi_i & \cos\alpha_i\cos\varphi_i \end{pmatrix} \tag{17}$$

Appendix 2: Adjoint method

The derivative operator $\nabla_{\mathbf{p}}$ used on any function $h(\mathbf{u}_{eq}(\mathbf{p}), \mathbf{p})$ is defined as:

$$\nabla_{\mathbf{p}} h = \frac{\mathrm{d}h}{\mathrm{d}\mathbf{p}} \tag{18}$$

Therefore,

$$\nabla_{\mathbf{p}} f = \frac{\partial f}{\partial \mathbf{u}_{eq}}\frac{\mathrm{d}\mathbf{u}_{eq}}{\mathrm{d}\mathbf{p}} + \frac{\partial f}{\partial \mathbf{p}}. \tag{19}$$

Calling $\mathbf{g}(\mathbf{u}, \mathbf{p}) = (\nabla_{\mathbf{u}} V)(\mathbf{u}, \mathbf{p})$, the definition of $\mathbf{u}_{eq}$ for every $\mathbf{p}$ gives:

$$\mathbf{g}(\mathbf{u}_{eq}(\mathbf{p}), \mathbf{p}) = 0 \quad \text{therefore} \quad \nabla_{\mathbf{p}}(\mathbf{g}(\mathbf{u}_{eq}(\mathbf{p}), \mathbf{p})) = 0, \tag{20}$$

leading to the following equation:

$$\frac{d\mathbf{u}_{\text{eq}}}{d\mathbf{p}} = -\left(\frac{\partial \mathbf{g}}{\partial \mathbf{u}_{\text{eq}}}\right)^{-1}\frac{\partial \mathbf{g}}{\partial \mathbf{p}}. \tag{21}$$

Using this result in Eq. (19) gives:

$$\nabla_{\mathbf{p}} f = -\frac{\partial f}{\partial \mathbf{u}_{\text{eq}}}\left(\frac{\partial \mathbf{g}}{\partial \mathbf{u}_{\text{eq}}}\right)^{-1}\frac{\partial \mathbf{g}}{\partial \mathbf{p}} + \frac{\partial f}{\partial \mathbf{p}} \tag{22}$$

The vector $-\frac{\partial f}{\partial \mathbf{u}_{\text{eq}}}\left(\frac{\partial \mathbf{g}}{\partial \mathbf{u}_{\text{eq}}}\right)^{-1}$, often called λ, is the adjoint vector. It is the solution of a linear system, faster to solve than an explicit finite difference calculation to access the gradient $\nabla_{\mathbf{p}} f$.

Appendix 3: Sensitivity study

In the proposed methodology, the spine balance was found by minimizing the total mechanical energy using EOS® medical images from patient follow-up as input data. We assessed the impact of uncertainties of clinical data numerization on numerical prediction.

The measurements errors were evaluated using ten numerizations of a single clinical image. The locations and orientations of seventeen vertebral bodies have been computed for each numerization. Inspired by Bayesian methodology, the geometry space was described with a probability law chosen to be normal, i.e., defined by mean value and standard deviation. The first and last decile of the distribution provided the envelops of the clinical geometry. The maximum distance between the envelops was evaluated at 5% of the maximum displacement from vertical spine in both frontal and sagittal direction.

The computation cost for the uncertainties propagation through the inverse problem was prohibitive. Therefore, we investigated the propagation of hypothetical uncertainties on the parameters, through the direct problem. The parameters uncertainties were chosen to be independent and following a normal distribution with a fixed mean and an arbitrary initial standard deviation (few percents of the mean). The deciles distribution of the computed equilibrium geometry $\mathbf{u}_{\text{eq}}$ was then compared with the deciles of clinical data from image numerization. The parameters standard deviation was iteratively updated to obtain a good match between clinical measurements envelops and equilibrium geometry envelops. After computation, the discrepancies between clinical envelops and equilibrium envelops was lower than 6% and was obtained with uncertainties on parameters characterized by standard deviation of 5% of the mean values.
