Abstract

CoBi₂O₄ (CBO) nanoparticles were synthesized by sol-gel method using Polyvinylpyrrolidone (PVP) as a complexing reagent. For a single-phase with the spinel structure, the formed gel was dried and calcined at four temperatures stages. Various methods were used to identified and characterized the obtained spinel, such as X-ray diffraction (XRD), Scanning Electron Micrograph (SEM-EDX), Transmission electron microscope (TEM), Fourier transform infrared (FT-IR), X-ray fluorescence (XRF), Raman and UV-Vis spectroscopies. The photocatalytic activity of CBO was examined for the degradation of a pharmaceutical product Cefixime (CFX). Furthermore, for the prediction of the CFX degradation rate an artificial neural network model was used. The network was trained using the experimental data obtained at different pH with different CBO doses and initial CFX concentrations. To optimize the network, various algorithms and transfer functions for the hidden layer were tested. By calculating the

mean square error (MSE), 13 neurons were found to be the optimal number of neurons and produced the highest coefficient of correlation R^2 of 99.6 %. The relative significance of the input variables was calculated and the most impacting input was proved to be the initial CFX concentration. The effects of some scavenging agents were also studied. The results confirmed the dominant role of hydroxyl radical $\text{OH}^\bullet$ in the degradation process. With the novel $\text{CoBi}_2\text{O}_4/\text{ZnO}$ hetero-system, the photocatalytic performance has been enhanced, giving an 80% degradation yield of CFX (10 mg/L) at neutral pH in only 3 hours.

Keywords: CoBi_2O_4 Spinel, Characterization, Cefixime, Artificial neural network, Optimization.

1. Introduction

In recent years, pharmaceutical compounds have sullied the aqueous environment, among those compounds, antibiotics are the major concern which are extremely dangerous because they are widely used in both human and veterinary medicines (Kaczala and E. Blum 2015). Antibiotics are also used to improve feed quality and thus increase rates in the poultry industries (World Health Organisation 2011). Analytical study of antibiotic use in 76 countries from 2010-2015 found that global antibiotic consumption has increased by 65% for the fifteen years studied (Sample 2018). The majority of antibiotic products are not biodegradable and their environmental contamination can increase aquatic toxicity (Mostafaloo et al. 2019). Generally, antibiotics are present at amounts ranging from ng/L to $\mu\text{g/L}$ in treated wastewater (Ibáñez et al. 2017; Shokoohi et al. 2017; Mirzaei et al. 2018). But even in small amounts, the presence of these compounds in water supplies will increase bacterial resistance, which produces a kind of micro-organisms called superbugs or antibiotic resistance (ABR) that are considered to cause very dangerous health effects (Elder et al. 2020). ABR is the ability to survive and multiply in the presence of antibiotic doses that are eventually deemed effective against a bacterial population or other microorganisms (Elder et al. 2020). A statistics study indicates that antibiotic resistance causes 700,000 deaths globally each year (Liu et al. 2019). ABR is now, in the 21st century, widely recognized as a grave threat to global health in the 21st century (Littmann et al. 2015).

As a typical example of antibiotics, Cefixime (CFX) was chosen which belonging to broad-spectrum, third-generation cephalosporin antibiotic derived semi-synthetically from the marine fungus *Cephalosporium acremonium* (Shooshtari and Ghazi 2017). CFX with molecular formula $C_{16}H_{15}N_5O_7S_2$ (Fig. 1) is (6R,7R)-7-[[[(2Z)-2-(2-amino-1,3-thiazol-4-yl)-2-(carboxymethoxyimino)acetyl]amino]-3-ethenyl-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid (Sheydaei et al. 2018). A study detected CFX as one of the most prevalent antibiotics observed in different water environments with concentrations of 278.65 to 422.1 ng/L (Mirzaei et al. 2018).

Fig. 1 Molecular structure of the antibiotic Cefixime.

Most of the conventional approaches that are commonly used for the removal of antibiotics have no positive findings for the degradation of antibiotic residues from contaminated waters or have substantial inconveniences such as by-products of the degradation (Xiong et al. 2018; Zhu et al. 2018; Zhang et al. 2020). On the other hand, Advanced Oxidation Processes (AOPs) have proven to be an effective solution for the rapid degradation of non-biodegradable substances in polluted water (Lou et al. 2017; Aboudalle et al. 2018; Kamagate et al. 2018). Particularly, the Heterogeneous photocatalysis process which is one of the best approaches for aqueous environment treatment as it is safer and a natural technology (used green energy). photocatalysis has proven on a previous investigations a successful degradation for various types of pharmaceutical drugs and organic compounds in the wastewater (Kamagate et al. 2018; Nguyen et al. 2018; Li et al. 2019b; Sayadi et al. 2019). Photocatalysis is based generally on the principle of the activation of a catalyst using an energy provided by a source of light (Homem and Santos 2011). As a catalyst, semiconductors are commonly used as they are very effective and easy to synthesize. Recently, many bismuth-based semiconductors have become very significant because of their high chemical stability, their excellent ability to absorb light and its narrow optical band gap (Tho et al. 2020). Cobalt bismuthate with the chemicals formula $CoBi_2O_4$ (CBO) was chosen as a typical semiconductor. To our knowledge, only one study has dealt with the synthesis and use of CBO photocatalyst (Jagadeesh and Sailaja 2019). Moreover, no study has been made yet concerning $CoBi_2O_4/ZnO$ hetero-system.

Artificial neural network (ANN) is one of the most powerful tools for modeling linear and non-linear systems (Mohammadzadeh Kakhki et al. 2020). It an effective way of predicting experimental patterns in various systems, especially for photocatalysis

(Zhou et al. 2020) Moreover, ANN has the self-learning ability and to work with incomplete knowledge, storing information on the entire network, having fault tolerance and a distributed memory (Kaur and Kaur 2014). Thus, modeling and optimization can be accomplished without the rigor of the experimental information via ANN (Ayodele et al. 2020). Owing to that, ANN has been employed in the prediction of photocatalysis CFX efficiency. The challenge in the ANN modeling is to build a network with the smallest possible number of random experimental points to modulate and achieve the expected results approach to real cases without designing an experimental model. Only a few studies have attempted this challenge (Hassani et al. 2015; Tabatabai-Yazdi et al. 2019; Zulfiqar et al. 2019). To find the most efficient and effective network, various algorithms and transfer functions for the hidden layer has been attempted.

In this study, we report the synthesis of CoBi_2O_4 nanoparticles which prepared by sol-gel auto combustion method using polyvinylpyrrolidone (PVP) as a complexing reagent. Various methods were used to identified and characterized the obtained spinel, such as XRD, SEM-EDX, TEM, FT-IR, XRF, Raman and UV-Vis spectroscopies. After that, Cefixime was considered as a model of antibiotic compound to tested the photocatalytic performance of this catalyst. The effect of pH, irradiation time, the concentration of CFX and concentration of catalyst on the degradation of CFX was examined and modeled using ANN. Also, a Garson formula was introduced to measure the relative significance of different input variables. After that, the effects of some scavenging agents have been studied. Finally, the new hetero-system $\text{CoBi}_2\text{O}_4/\text{ZnO}$ has been tested in order to enhance the photocatalytic performance.

2. Material and methods

2.1 Chemicals

Chemicals used in the present study were bismuth nitrate pentahydrate $[\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}]$ (98.5% Chem-Lab), cobalt nitrate hexahydrate $[\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}]$ (98% Biochem), Zinc nitrate hexahydrate $[\text{N}_2\text{O}_6\text{Zn} \cdot 6\text{H}_2\text{O}]$ (98% Biochem), Cefixime trihydrate and Polyvinylpyrrolidone were obtained from a pharmaceutical company Pharmalliance Algeria, ethanol from Biochem, Sodium hydroxide, Hydrochloric acid, isopropanol and nitric acid were supplied by Sigma Aldrich. All chemicals were used as received without further purification. Distilled water has been used as a solvent.

2.2 Synthesis of CoBi₂O₄ nanoparticles

CoBi₂O₄ was synthesized by the aqueous PVP sol-gel method. The gel was prepared using stoichiometric amounts (1:2 ratio) of cobalt nitrate hexahydrate [Co(NO₃)₂·6H₂O] and bismuth nitrate pentahydrate [Bi(NO₃)₃·5H₂O] respectively. They were then dissolved in ethanol by using a magnetic stirrer; an excess of 5% citric acid was added in the solutions. After total solubilization, both solutions had been mixed and heated at 50 °C for 1h.

In the following step, Polyvinylpyrrolidone (PVP K30), used as a complexing agent was dissolved in 50 mL water and added to the reaction solution, applied about 15% w/w to obtain the complexing role (Giannopoulou et al. 2015). After concentrating the solutions by evaporation at 80 °C under stirring, the mixed solution turned into a reddish transparent gel. After drying and combustion at 200 °C for 6 h a precursor gel powder was formed (Xerogel).

The amorphous powder was subjected to calcination at 300°C, 400°C, 600°C and 800°C in an air oven each one for 3 h. The synthesized sample was annealed to improve the degree of crystallinity and to eliminate any leftover carbonated waste after the combustion reaction. Then, it was subjected to phase identification, microstructural analysis and photocatalytic studies.

2.3 Characterization

The XRD analysis of the products was recorded by a Phillips PW 1730, X-ray diffractometer using monochromatized Cu K radiation ($\lambda = 0.15417$ nm) the morphology of the sample SEM was studied using the electron scanning microscope FEI Quanta 650 equipped with EDX and Mapping analysis with 20 kV accelerated voltage. Transmission electron microscope (TEM) images of the nanostructures were taken on a JEOL-24011BU. ATR-FTIR spectra were obtained in the range of 400–4000 cm⁻¹ with an Alpha Bruker spectrometer (One FTIR model). The chemical analysis was carried out by using X-ray fluorescence (PANalytical epsilon3-XL spectrometer). UV–visible diffuse reflectance spectrum (DRS) of the sample was produced by dry pressed disk sample using Cary 5000 UV–vis. The Raman analysis was carried out using LabRAM HR Evolution system Horiba Jobin-Yvon.

2.4 Photocatalytic degradation study

We selected (CFX) as a pharmaceutical model contaminant to investigate CoBi₂O₄'s photocatalytic performance. The photocatalytic degradation of CFX was conducted by mixing an appropriate quantity of CoBi₂O₄ in 100 mL of CFX solution with known concentration. The pH was set to the desired value with NaOH and HCl. The solution was continuously stirred for 2h in dark conditions in a closed reactor to reach the balance of adsorption and desorption before switching on the light. As a visible light source, a tungsten bulb 200 W manufactured by Osram was applied and positioned at 10 cm from the solution surface. The intensity (8.25 mW/cm²) and the maximum emission (630 nm) of the lamp were measured by a digital flux meter (Testo 545). A cooling system consisting of a double-walled reactor attached to a thermostatic bath (Daihan Labtech, LCB-11D) has been used to maintain the temperature of the solution nearly constant (25 ± 1 °C) during the photocatalytic experiments. At a regular time, 2 mL of the solution was centrifuged at the speed of 5,000 rpm for 10 min to filter the suspended CoBi₂O₄ particles from the sample and directly analyzed by UV-Visible spectrometry (OPTIZEN, UV-3220UV) at the maximum absorption wavelength of CFX (288 nm). It should be mentioned that the small positive error of UV-Visible spectrometry in comparison with HPLC was ignored. The following equation was used to calculate the degradation rate of CFX.

$$\text{Photodegradation}\% = \frac{(C_o - C)}{C_o} \times 100 \quad (1)$$

Where C_o is the initial concentration of CFX after adsorption and C is the concentration of CFX at time t.

As already mentioned, the CFX concentration was monitored by measuring the absorbance of the samples using a UV–Visible spectrophotometry. The degradation of the pollutant was followed by the disappearance of the band corresponding to CFX at 288 nm as shown in figure 2. The experiment was conducted in the presence of 0.1 g CBO at pH 6, room temperature and an initial CFX concentration of 10 mg/L.

To evaluate the CFX mineralization by the catalyst CBO, the amount of total organic carbon (TOC) in the solution at a regular time with the same conditions was measured by TOC analyzer (Shimadzu TOC-L, Japan) using the catalytic combustion

method at 680°C. The results of TOC analysis are presented in Fig. 2 (b). The following equation was used to calculate the TOC removal (%):

$$TOC_{removal}\% = \frac{(TOC_o - TOC)}{TOC_o} \times 100 \quad (2)$$

where TOC_o (mg) is the initial TOC values after adsorption, TOC (mg) is the remaining TOC in solution.

the TOC removal reached 67.23% in the presence of CBO catalyst after 6 h, which confirmed that cefixime could be effectively mineralized in the presence of CBO photocatalyst under visible light irradiation.

Fig. 2 (a) UV–visible spectra (B)TOC removal of CFX (10 mg/L).

2.5 Experimental design and modeling

The input layer consisted of four numbers of neurons, which are pH, irradiation time (min), the dose of CBO (g/L) and concentration of CFX (mg/L), while photodegradation of CFX (%) was selected as the output layer. The application was performed in the laboratory to obtain the actual responses. As it is a challenge to build a network with the smallest possible number of random experimental points to approach to real cases without designing an experimental model. For that, a total of 40 random experimental points has been randomly divided into 70% training, 15% testing and 15% validation data. Training data were presented to the network during training. The use of validation data was to test network generalization and to stop training if generalization stops. The test data provided a fully independent network performance measurement during and following training (Ayoubi-Feiz et al. 2019).

The modeling of the photodegradation of CFX was carried out by MATLAB R2014a which has been widely used (Medarević et al. 2016; Ayoubi-Feiz et al. 2019; Tabatabai-Yazdi et al. 2019; Zulfiqar et al. 2019; Garg et al. 2020). The model parameters are described in Table 1. For the model development, the feed-forward neural network with backpropagation method was used. Furthermore, a supervised learning technique called Levenberg-Marquardt with a training function 'trainlm' has been used for training the network.

Table 1 ANN model parameters.

The number of hidden neurons is a critical element of modeling experimental processes with ANN (Hazrati et al. 2017). For its optimization, a set of topologies have been used in which the number of hidden neurons changed from 2 to 20. The mean square error MSE was performed to investigate the relation between the hidden neurons and the network error (Ayoubi-Feiz et al. 2019). The MSE function was used as Eq.3. The coefficient of correlation R (Eq.4) used to predict model conformity and applicability, the more the value is close to one, the better it is applied.

$$MSE = \frac{1}{n} \sum_{i=1}^n (y_{i,NN} - y_{i,exp})^2 \quad (3)$$

$$R^2 = 1 - \frac{\sum_{i=1}^n (y_{i,NN} - y_{i,exp})^2}{\sum_{i=1}^n (y_m - y_{i,exp})^2} \quad (4)$$

where n is the total number of data points, $y_{i,NN}$ and $y_{i,exp}$ are the network prediction and the experimental response and i is an index of the data, y_m is the average of the actual values.

3. Results and discussion

3.1 Characterization of the catalyst

To confirm the single phase of CoBi_2O_4 , an X-ray diffraction (XRD) pattern after each calcination was taken. Figure 3 illustrates the effect of different annealing temperatures on the structure of the synthesized samples. The pure CoBi_2O_4 nano-powders were obtained at 800 °C (after annealing at 300 °C, 400 °C, 600 °C) almost a single phase of CBO without impurity was observed. The phase of the CoBi_2O_4 could be indexed with the five main diffraction peaks at $2\theta = 27.88^\circ$ (111), 33.12° (200), 45.72° (220), 52.76° (311) and 56.04° (222) which were in good agreement with the reference peaks (Jagadeesh and Sailaja 2019) almost the same, and also in line with the standard card (JCPDS 50-0369) from Joint Committee of Powder Diffraction Standards of the face-centered cubic of CoBi_2O_4 .

The crystallite size was calculated from the main diffraction peaks of the last calcined product (at 800 °C) with the following Debey- Scherer formula Eq. (5). The crystalline sizes have been estimated between 19.45 and 46.39 nm.

$$D = \frac{K\lambda}{\beta \cos(\theta)} \quad (5)$$

where D is the crystallite size of the phase in nanometers, K is the Scherrer constant. ($K = 0.94$ for cubic symmetry), λ is the wavelength of the X-ray beam used, β is the full width at half maxima (FWHM) in radians and θ is the Bragg's angle.

Fig. 3 XRD diffractogram of CoBi_2O_4 calcined at (a) 300°C, (b) 400°C, (c) 600°C and (d) 800°C.

For the XRD patterns of the ZnO nanoparticles prepared via co-precipitation. As shown in Figure 4, the ZnO nanoparticles displayed a Wurtzite structure (hexagonal phase, space group $P6_3mc$). All standard peaks observed for ZnO nanoparticles were in line with those obtained from (JCPDS 36-1451) (Raou 2017).

Fig. 4 XRD diffractogram of ZnO.

The spinel structure may be considered as a continuously bound crystal in which the atoms are bonded by equivalent forces (ionic, covalent or van der Waals) to all nearest neighbors. The spinel shaped metal ions are found in two separate sub-lattices known as A-site (tetrahedral) and B-site (octahedral), as stated in the geometric arrangement of the nearest oxygen neighbors (Sabri et al. 2016). Fourier transform infrared spectra of CoBi_2O_4 recorded within the range of 4000–400 cm^{-1} are shown in Figure 5. It is evident in the IR spectrum that CBO had five intensive absorption peaks in the region of 400–900 cm^{-1} , which could be related to the typical metal-oxygen (M–O) vibrations (Jasaitis et al. 2011). The presence of peaks between 570 cm^{-1} and 669.9 cm^{-1} belonged to the vibration of the Bi–O bond and the vibration peak at 824.28 cm^{-1} can be assigned to Bi–O–Bi (Yang et al. 2018; Viruthagiri and Kannan 2019). Furthermore, the appearance of Peaks 446.13 cm^{-1} and 532.31 cm^{-1} can probably be related to the tetrahedral (CoO_4) in the spinel (Sousa et al. 2019).

Fig. 5 FTIR spectra of CoBi_2O_4 .

Figure 6 shows the Raman spectra of CoBi_2O_4 . There are five Raman-activated bands; all these modes were observed at ambient conditions. The bands above 600 cm^{-1} were due to the motion of oxygen in the tetrahedral AO_4 octahedral BO_6 groups (Li et al. 2019a), suggesting a certain amount of Co and Bi disturbance in the tetrahedral and octahedral sites. The low-frequency modes observed at 54.13, 80.5 and 123.73 cm^{-1} can be related to the Bi^{3+} ion motion in the spinel layer and the mode at 521.03 cm^{-1} can be attributed to the variation of bond distances between Bi atoms

and the spinel block apical O atoms (Zhang et al. 2018). The strongest band observed at 264 cm^{-1} corresponded to O–Bi–O vibration (Zhang and Saxena 2013). The Raman modes of 193.29 , 476.05 , 600 and 670 cm^{-1} were related to the vibration of the Co atoms (Diallo et al. 2015). Besides, a small Raman band was observed at 151.35 cm^{-1} ; the origin of this band is still unknown.

Fig. 6 Raman spectra of CoBi_2O_4 .

The morphology and structures of the prepared sample were visualized by Scanning Electron Micrograph (SEM) and transmission electron microscope (TEM) techniques were used. Figure 7 (a) shows a typical SEM image of the sample. It can be observed that the sample consisted of particles exhibiting cubic morphology. Due to the ultrafine nature of the sample, these particles displayed a slightly agglomerated morphology. The TEM images of CoBi_2O_4 shown in figure 7 (b) demonstrate clear information regarding the size, shape and size distribution of nanoparticles. Based on the size distribution histogram in the inset figure, the catalyst was composed of particle size in the range of 22 nm . It was found that the size of the crystallite obtained from XRD analysis and the particle size obtained from TEM analysis were in the same size order. This picture also shows the existence of several aggregations within the range of nanometres.

The electron diffraction pattern of the nanoparticles are shown in figure 7 c, This pattern has a cubic shape and right angles ($K/H = 1$, $(\vec{H}, \vec{K}) = 90^\circ$) which is defined as a cubic face-centered CFC type of crystalline spinel (Andrews KW , Dyson DJ 1967) and that confirmed the XRD results.

Fig. 7 SEM (a) TEM (b) Diffraction pattern (c) of nanoparticles CoBi_2O_4 .

The elementary study of the CoBi_2O_4 nanoparticles was carried out by Energy Dispersive X-ray spectrometer (EDX). The peaks for Co, Bi and O elements were clearly observed in the EDX image, as shown in figure 8 (a). The atomic percentage of the elements in the sample are given in the inset Table of the EDX data. The atomic percentages of Co, Bi and O were estimated to be 14.02% , 26.25% and 59.73% , respectively. The quantification of Co, Bi and O confirmed that the atomic ratio of Co:Bi:O was $1.00:1.87:4.26$, which agrees with the theoretical stoichiometric composition of CoBi_2O_4 .

X-ray fluorescence measurements (XRF) spectra figure 8 (b) showed that Co and Bi were the most abundant elements. Regarding silver (Ag), it was used in the XRF analysis method. The inset Table of the XRF results shows that the weight percentage of CoO and Bi₂O₃ was estimated to be (14.109%) for CoO and (85.89%) Bi₂O₃. The molar mass was then calculated for CoO and Bi₂O₃ and found to be 74.93 and 467.96 g/mol, respectively. This confirmed that the atomic ratio of Co:Bi:O was 1.00:1.95:3.93, which agrees with the theoretical stoichiometric composition of CoBi₂O₄ and also in line with the EDX analysis.

Fig. 8 Energy dispersive X-ray (a) X-ray fluorescence (b) diffractogram of nanoparticles CoBi₂O₄.

The elemental mappings in figure 9 were located in the same EDX region. The colored map of the SEM image (where Co, Bi and O are given in colors like Green, Red and Blue, respectively) revealed that Co, Bi, and O elements coexisted and were uniformly distributed.

Fig. 9 EDX elemental mapping images of CoBi₂O₄ a) All elements b) Cobalt c) Bismuth d) Oxygen.

Optical properties of CoBi₂O₄ nanostructure were measured using the UV–Vis diffuse reflectance spectrum. As shown in figure 10, the bandgap was estimated as 2.5 eV which is lower than that of TiO₂ and ZnO (3.2 eV) (Serpone 2006; Miki-yoshida 2016). This indicates that CBO has an excellent absorption level in the wavelength range from 300 to 800 nm that contains both UV and visible light, which appears more efficient than ZnO and TiO₂, leading to an increase in the formation of electron-hole pairs on the photocatalyst's surface in visible light irradiation.

Fig. 10 UV–Vis optical absorption edges.

3.2 Artificial neural network modeling of the elimination of Cefixime

For the modeling, irradiation time, pH, initial CFX concentration and CBO catalyst dose were selected as the input variables and the related degradation rate of CFX was the output variable. To feed the structure of the ANN, a total of 40 experimental sets were used. The data sets have been divided into 70% training, 15% validation and 15% test, as shown in Table 2.

Table 2 Data sets of experimental results and ANN's predicted results.

The essential part of the neural network architecture is the choice of the number of hidden neurons. The model's best performance comes when the mean square error (MSE) determined using equation (2), is the smallest.

Fig. 11 Impact of the number of hidden neurons on the MSE of the neural network.

Figure 11 shows that the Levenberg-Marquardt with a training function 'trainlm' and 13 hidden-layer neurons produced the highest correlation coefficient $R^2 = 0.996$ and the smallest MSE value 1.81×10^{-4} . The relation of experimental data to ANN model predictions can be derived from the contrast between the experimental data and the predictions of the ANN model (Fig.12). The training data were given as the model's input values, and the simulation output was compared with the relevant experimental data. The adaptation of the model results to experimental data for the training data set was very successful. The main part of model validation is the testing of network performance for the testing data set access, the correlation coefficient was likewise very high in this case $R_{\text{test}}^2 = 0.977$.

Fig. 12 The relation of experimental data to the ANN model's predictions for each type of data.

3.2.1 Effect of pH

The pharmaceuticals polluted water is discharged in the environment at variable pH values; consequently, it is necessary to investigate the role of pH on the photocatalytic degradation. For this purpose, photodegradation experiments have been carried out in 100 ml of 10 mg/L CFX solution at a fixed CBO amount of 0.1 g and 360 min irradiation. Three different initial pH was selected and kept constant by adding HCl or NaOH. The degradation rate of CFX increased with the increase of the pH value of the solution from 4 to 6 and then decreased from 6 to 8, as observed in figure 13 (a). Based on these results, it can be deduced that the photodegradation of CFX was optimal at pH = 6. It is difficult to grasp pH impact on the performance of the photocatalytic degradation process because of its multiple roles, such as the neutral electrical charge of the CFX molecules, as well as the protonation and the electropositive surface of CBO. This may also be related to the reaction between organic compounds and dissolved oxygen (Abbasi and Hasanpour 2017). The improvement of the photocatalytic activity of the catalyst at pH = 6 can probably be related to the charge accumulation on the external surface (Bai et al. 2017). So, the

pH change may therefore affect the dispersion of the catalyst in the suspension. Moreover, figure 13 (b) shows that the values predicted by the ANN model were well in line with the experimental data.

3.2.2 Effect of the catalyst dose

The effect of CBO catalyst dose on the photodegradation activity of CFX was examined. A set experiment was conducted by using a catalyst dose ranging from 0.05 to 0.15 g in 100 mL of solution for 15 mg/L of CFX at pH = 6 and 360 min irradiation. Figure 13 (c) illustrates the effect of the catalyst dose on the CFX photodegradation removal, showing that the degradation of CFX increased from 66% to 72% for an increase of the catalyst dose from 0.05 to 0.08 g because of the limited active sites available on the CBO catalyst surface. However, the degradation efficiency of CFX decreased beyond this amount of catalyst, namely from 0.08 to 0.15 g. This may be attributed to the fact that the accumulation of free catalysts leads to an increase in the opacity of the solution and a decrease in light penetration. This is due to a scattering effect for an expansion of the dose of catalyst (Zhou et al. 2018). Therefore, the optimal dosage of the catalyst for CFX photodegradation was selected to be 0.08 g. Based on the obtained results shown in figure 13 (d), the results predicted by the ANN and the experimental values were well agreed.

3.2.3 Effect of the initial CFX concentration

For the purpose, the photodegradation studies were performed by varying initial concentrations of CFX from 5 to 15 mg/L in 100 ml of the solution with 0.1 g of the CBO catalyst at pH 6 after 360 min of irradiation time under visible light. Figure 13 (e) shows that by raising the CFX concentration, the degradation yield decreased from 82 to 55%. This behavior can be related to the diminishing number of available sites on the catalyst CBO surface. Therefore, a high number of CFX molecules would have an inhibitory effect on the photodegradation efficiency due to the lack of any direct contact between the CBO catalyst surface and CFX. Besides, many photons could be absorbed by the CFX molecules and hence did not reach the catalyst surface. The comparison between ANN predicted values and the experimental data shown in figure 13 (f) revealed a good agreement between them.

Fig. 13 (a) effect pH (c) effect of catalyst dose (e) effect of initial CFX concentration
(b,d,f) Comparison of the experimental results with the predicted ANN values for
various operating parameters.

3.2.4 The relative significance

An evaluation process based on the network weight matrix and the Garson's equation (Garson 1991) was applied to calculate the relative significance of the input variables on the network's output. The relative significance of input variables influencing the CFX photodegradation values has been calculated by equation 6 (Ibrahim 2013).

$$RI_X = \frac{\sum_{x=1}^n |w_{xy}w_{yz}|}{\sum_{y=1}^m |w_{xy}w_{yz}|} \quad (6)$$

where RI_X is the relative significance, n and m are respectively the input numbers and hidden neurons. w_{xy} are the connection weights, $\sum_{y=1}^m |w_{xy}w_{yz}|$ is the sum of the product of the final weights of the connections from input neurons to hidden neurons along with the links from hidden neurons to output neurons (Ibrahim 2013).

Table 3 ANN model's weight and bias matrix.

The ANN model's weight matrix is given in Table 3, while the relative significance of the input variables derived from equation (4) is displayed in figure 14. As can be seen, the initial CFX concentration showed the most significant impact on the performance of CFX photodegradation (28%) compared with the other operating factors, namely CBO dosage (27%), irradiation time (24%) and pH (21%).

Fig. 14 The relative significance of the inputs on CFX degradation.

3.3 Effect of scavenging agents and the photocatalytic mechanism

Generally, the photodegradation of organic compounds by a catalyst semiconductor can be described by different reaction pathways regulated by different active species such as $\text{OH}^\bullet$ hydroxyl radical, superoxide $\text{O}_2^\bullet$, and photogenerated electrons and holes e^-/h^+ pairs which called reactive oxidant species (ROS) (Zuo et al. 2017). To investigate the dominant ROS on the photodegradation of Cefixime over the CBO catalyst and for an understanding of the photocatalytic mechanism, several active species trapping tests were run in the presence of different concentrations of some

scavengers. Each of the scavenging species was chosen for a specific type of photocatalytic radicals. p-Benzoquinone BQ was used as superoxide $O_2^{\bullet}$ radical quencher (a scavenger for superoxide anion radical) (Nithya and Ayyappan 2020), Potassium dichromate $K_2Cr_2O_7$ was used as a scavenger for electron (e^-) (Gupta et al. 2020), Disodium ethylenediaminetetraacetic acid (Na_2 -EDTA) was used as a scavenger for the hole (h^+) and as photoinduced h^+ acceptor (Tho et al. 2020) and isopropanol (IPA) alcohol was employed as an $OH^{\bullet}$ scavenger (hydroxyl $OH^{\bullet}$ radical quencher) (Ghattavi and Nezamzadeh-Ejhieh 2020). The tests were performed with an initial Cefixime concentration of 5 mg/L, at pH 6, and using CBO with a solution ratio of 0.8 g/L. The impact of these scavenging agents (quenchers) on the photodegradation efficiency of CBO nanocomposite was shown in Fig 15.

Fig. 15 Effect of different scavengers on photocatalytic degradation of CFX over CBO photocatalyst.

The obtained results are summarized in the next order of the photodegradation efficiency in the presence of different scavengers: Sample without the scavengers (Free) (79 %) > $K_2Cr_2O_7$ (64%) > p-Benzoquinone (59%) > Na_2 -EDTA (40%) > Isopropanol (25%). As shown, the most decrease in the degradation efficiency was observed by Isopropanol which confirmed that the generated $OH^{\bullet}$ has a dominant role in the degradation of CFX. $OH^{\bullet}$ radicals are strong, active and unselected oxidizing species for organic substrates in terms of oxidative degradation (Kumar et al. 2020). Then it comes Na_2 -EDTA, this indicates that both $OH^{\bullet}$ and h^+ are the major active species. However, in the presence of p-Benzoquinone, only a small effect has been observed on the CFX photodegradation. This indicates that $O_2^{\bullet}$ was a minor active species. The effect of $K_2Cr_2O_7$ was so small that it neglected the electron e^- role in the CFX degradation. According to these results, the following pathways (Fig. 16 and equations 7,8,9 and 10) were suggested for the photodegradation of CFX onto CBO.

Fig. 16 Proposed mechanism for CFX degradation in the presence of $CoBi_2O_4$ nanoparticles.

3.4 Comparison of Cefixime photodegradation by different processes

In order to enhance the photocatalytic performance of CFX by synthesized CBO nanoparticles and also to eliminate the photolysis effect, a set of experiments have been tested in the same condition as illustrated in fig.17. The experiment was conducted in the presence of 0.1 g catalyst at pH 6, room temperature and an initial CFX concentration of 10 mg/L. In the absence of the catalyst, a very small degradation rate of CFX by photolysis can be observed, lower than 5%. On the other hand, in the presence of the CBO photocatalyst, the degradation rate of CFX reached 60 % within 3 h. The hetero-systems can increase the rate of photo-activity by extending the spectral photo response of wide band semiconductors toward the visible light region, as already demonstrated in recent works (Belaissa et al. 2016; Boumaza et al. 2016; Rekhila et al. 2017; Boutra et al. 2019). For that, the new hetero-system $\text{CoBi}_2\text{O}_4/\text{ZnO}$ has been tested. Different weight ratios of the two catalysts CBO and ZnO were tested to examine the impact on the CFX photodegradation. As can be seen in fig.17, the high photodegradation efficiency was noticed at ratio of 50%/50% weight percentage of the hetero-system $\text{CoBi}_2\text{O}_4/\text{ZnO}$, leading to an 80% degradation efficiency within only 3 h.

Fig. 17 Time-course of the CFX degradation by different processes.

4. Conclusion

In summary, in the present work, CoBi_2O_4 nanoparticles were successfully synthesized by the sol-gel method and then characterized by both spectroscopic and morphological tools. The catalysts prepared were tested for CFX antibiotic degradation. The photocatalytic degradation of CFX was modeled successfully using an artificial neural network (ANN). A feed-forward neural network with backpropagation method and a Levenberg-Marquardt method was used. The degradation of CFX in different operating conditions was predicted with 13 hidden neurons. The results showed that the CoBi_2O_4 nanoparticles led to an 86 % CFX photodegradation yield in the following optimal condition, pH = 6, 5 mg/L CFX, 0.8 g/L catalyst dose and 360 min of irradiation. It was shown that all the parameters of the study (irradiation time, pH, initial concentration of CFX and catalyst dose) have a significant effect on the CFX photodegradation.

However, the main effect was the CFX's initial concentration. Moreover, the effects of some scavenging agents were studied and the results confirmed the dominant role

of hydroxyl radical OH• in the CFX degradation process. Finally, the new CoBi₂O₄/ZnO hetero-system was discussed and demonstrated a rapid degradation efficiency of 80 % in just 3 hours. Owing to these promising preliminary results, it will be further considered in future works.
