Abstract

In this work, interactions of carboxylated core shell magnetic nanoparticles with polymyxin B sulfate were studied by connecting capillary electrophoresis with inductively coupled plasma mass spectrometry. The interaction was probed by affinity mode of capillary electrophoresis with 25 mM phosphate buffer at physiological pH. ^{54}Fe , ^{56}Fe , ^{57}Fe , ^{34}S , and ^{12}C isotopes were used to monitor the migration of an electroosmotic flow marker and the interaction of the nanoparticles with polymyxin B. The analysis of interaction data showed two distinct interaction regions, one with low polymyxin B concentration, the second with high polymyxin B concentration. These regions differed in the strength of the interaction, $14.9 \times 10^6 \text{ M}^{-1}$ and $16.0 \times 10^3 \text{ M}^{-1}$, and in the stoichiometry of 0.7 and 3.5, respectively. These differences can be explained by the decrease of electrostatic repulsion between nanoparticles caused by polymyxin B. This is also in agreement with the nanoparticles peak shapes: sharp for low polymyxin B concentrations and broad for high polymyxin B concentrations.

1 Introduction

The recent developments in nanotechnology and the emerging use of various types of nanoparticles (NPs) in industry, environment or medicine have raised questions about the behavior of NPs when in the presence of other (bio)molecules as well as concerns about their potential impact on human health. Although the chemical composition of nanomaterials may not be significantly different from bulk materials, their physicochemical properties and their interactions with biological systems dramatically change due to their nanoscale dimension [1]. Currently, there is a strong demand for the development and validation of new high-throughput methodologies that are reliable and accurate for the characterization and quantification of NPs in various kinds of biological samples. As it has already been reported, NPs can interact with many (bio)molecules (such as proteins, DNA, etc.), and the resulting NPs coat could form a protective layer that can increase NPs stability, water solubility and biocompatibility [2, 3]. The protein corona causes numerous biological responses of NPs, such as facilitating cell internalization [4]. Protein binding is also one of the key aspects affecting the biodistribution of NPs throughout the body [5]. This can be beneficial for applications such as diagnosis or drug delivery. However, it was found that NPs can initiate and catalyze protein aggregation, denaturation and misfolding [6, 7] and can, moreover, disrupt protein–protein interactions [8], possibly resulting in protein malfunctioning and, therefore, adverse biological effects [9].

As mentioned, the study of non-covalent molecular interactions is important due to their high significance in various (bio)chemical and biological processes. Strength of the non-covalent interactions between two interacting compounds, ‘A’ and ‘L’, is characterized by the apparent binding (association) constants that are defined by the following:

$$K_b = \frac{[AL]}{[A][L]} \quad (2)$$

Here, [A], [L] and [AL] are equilibrium molar concentrations of analyte, ligand and their complex, respectively.

These constants can be determined by a variety of physico-chemical methods [10–15]. Here, capillary electrophoresis (CE), which is well known not only as an efficient separation technique but also as a viable tool to study chemical reactions, including kinetic measurements and the analysis of chemical equilibria [16], features several benefits such as

1 high separation efficiency, short analysis time periods, high mass sensitivity, very low
2 chemical and sample consumptions and the characterization of interacting species in a
3 solution [17]. Therefore, CE in the affinity capillary electrophoresis mode (ACE) is a
4 powerful technique for the characterization of NPs and their interaction with other
5 (bio)molecules [18–25]. In ACE, increasing amounts of ligands are simply added to the
6 running buffer, leading to changes in the migration time of the interacting analyte. The
7 binding constant between the ligand and the analyte is then calculated from the effective
8 mobilities of the analyte [10, 26–28].

9
10 However, sometimes CE is not applicable in complex media because of matrix interference,
11 and thus requires complex sample preparation procedures. Moreover, the benefits of CE can
12 be overshadowed by the low sensitivity of UV detection systems, which are commonly used
13 [29, 30]. This can be solved by coupling of a CE with an electrospray ionization mass
14 spectrometry (ESI-MS), which can directly provide stoichiometric information on the
15 complex and simultaneously detect several components [12]. However, the major problem in
16 connecting CE with ESI-MS lies in the necessity of using volatile “MS-compatible” running
17 buffers and migration systems in CE, since the non-volatile components do not reach the ESI
18 source [31].

19
20 Nevertheless, another interesting possibility exists that can solve these issues: CE connected
21 to inductively coupled plasma mass spectrometry (ICP-MS). ICP-MS is capable of achieving
22 multi-element determination of ultra-trace concentration levels of metal and metalloid
23 containing compounds. In addition to its low detection limits and excellent sensitivity, the
24 linear dynamic range of ICP-MS allows for the simultaneous detection of both major and
25 trace components at the same sample dilution [32, 33]. Therefore, CE-ICP-MS seems to be
26 one of the few analytical tools that can be employed to understand the fate of metal-based
27 drugs in the body and the body’s mechanisms of action at the molecular level, as well as in
28 metabolomic analysis [34, 35]. Moreover, CE coupled with ICP-MS still provides
29 stoichiometric, thermodynamic and kinetic information about the interactions between metal
30 species and (bio)molecules [36–38]. Additionally, CE interfaced with ICP-MS has shown a
31 strong potential for directly analyzing nanomaterials in complex media without any extraction
32 or extensive sample preparation steps [39].

In the work presented here, the interactions between carboxylated core-shell magnetic NPs ($\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH NPs) and polymyxin B sulfate were analyzed using CE-ICP-MS. CE-ICP-MS was chosen because it allows detecting specific metal species and hence it can be used for correct determination of migration times of interacting species (in comparison with CE-DAD). Polymyxin B, an antibiotic primarily used to treat resistant bacterial infections, was selected as a model antibiotic in the view of development a microdevice to test bacterial resistance. The microbial resistance to antibiotics represents a huge well-known problem in medicine related to the excessive use of antibiotics as well as unhealthy life style [40]. It is interesting that a lot of NPs have antibacterial activity [41], however, resistance of bacteria to NPs was also described [42]. The microdevice, schematically shown in Fig. S1 in the supporting material, is based on the formation of 3D-printed straight channel, its insertion into PDMS and its removal [43]. The NPs with polymyxin B are captured in the device by using magnetic field and when they are in contact with bacterial cells, they are releasing polymyxin B according to the cells' resistance. In order to proof and tune the performance of the microdevice, the quantitative description of the interaction of $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH NPs with polymyxin B is necessary. Interestingly, the results can be also used in the case of application of these NPs for the treatment of wastewaters contaminated by antibiotics [44, 45].

2 Experimental

2.1 Chemicals

All the chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA), except for polymyxin B sulfate, which was from SERVA (FeinBiochemica, Heidelberg/New York) and 2-[methoxy(polyethyleneoxy)propyl]-trimethoxysilane, which was from ABCR (Karlsruhe, Germany). A single element aqueous calibration standard of Fe ($c = 1,000 \pm 2 \text{ mg.L}^{-1}$) diluted to $100 \text{ }\mu\text{g.L}^{-1}$ was purchased from ASTASOL (Analytika, Prague, Czech Republic) for the fine tuning of ICP-MS parameters. Tuning solution of Li, Y, Ce and Tl ($c = 1 \text{ }\mu\text{g.L}^{-1}$) was purchased from Agilent Technologies (Tokyo, Japan). The background electrolytes (BGEs) were prepared by dissolving the needed amount of phosphoric acid and adjusting the pH of this solution to 7.4 with NaOH. Ultrapure water (resistivity of $18.2 \text{ M}\Omega\text{.cm}$, MilliQ, Millipore) was used to prepare all solutions.

2.2 Synthesis and characterization of nanoparticles

The $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH NPs were synthesized according to reported protocols [46, 47].

In brief, magnetic maghemite NPs (γ -Fe₂O₃, 7 nm mean diameter) were prepared following the procedure described by Massart and were subsequently coated with citrate anions [48, 49]. Citrated maghemite NPs ($V = 300 \mu\text{L}$, $n_{\text{Fe}} = 4.0 \times 10^{-4} \text{ mol}$) were coated with a thick silica shell by condensing tetraethylorthosilicate ($V = 600 \mu\text{L}$, $n = 2.7 \times 10^{-3} \text{ mol}$) in the presence of ammonia ($V = 1.25 \text{ mL}$, $n = 1.9 \times 10^{-2} \text{ mol}$) in a mixture of water ($V = 25 \text{ mL}$) and ethanol ($V = 50 \text{ mL}$). The silica shell surface functionalization with NH₂ groups and short polyethyleneglycol (PEG) chains was performed in a second step by the simultaneous condensation of (3-aminopropyl)triethoxysilane ($V = 100 \mu\text{L}$, $n = 4.2 \times 10^{-4} \text{ mol}$) and a silica PEG-derived compound, 2-[methoxy(polyethyleneoxy)propyl]trimethoxysilane ($V = 230 \mu\text{L}$, $n = 4.2 \times 10^{-4} \text{ mol}$), with an appropriate amount of tetraethylorthosilicate ($V = 200 \mu\text{L}$, $n = 8.97 \times 10^{-4} \text{ mol}$) in order to generate a cross-linked silica shell. The NPs were then dispersed in 25 mL of 3-(N-morpholino)propanesulfonic acid (MOPS) buffer at 0.1 M at pH 7.4. The Fe₂O₃@SiO₂ NH₂ NPs were then converted to Fe₂O₃@SiO₂ COOH NPs via an overnight reaction of 11 mL of this dispersion of NPs with succinic anhydride ($m = 1.438 \text{ g}$, $n = 1.4 \times 10^{-2} \text{ mol}$). Finally, the NPs were washed with MOPS buffer in PD-10 columns containing Sephadex G-25 (GE Healthcare).

The iron concentration in the Fe₂O₃@SiO₂ COOH NPs was measured to be $7.8 \times 10^{-3} \text{ mol.L}^{-1}$. The NPs were then characterized by atomic force microscopy (AFM), dynamic light scattering (DLS) and zetametry. Dimension Icon atomic force microscope (Bruker, Santa Barbara, USA) with NanoScope 9.1 software was employed for topography measurement. The NP sample was diluted 10,000 times with deionized water from a stock dispersion of Fe₂O₃@SiO₂ COOH NPs. Of this sample, 5 μL were deposited on a freshly cleaved mica substrate (SPI Chem Mica, grade V-4 muscovite, SPI supplies) and left to dry in a desiccator. A ScanAsyst Air AFM tip with a reflective Al coating on the cantilever back side (nominal resonant frequency 70 kHz and nominal force constant 0.4 N.m^{-1}) was used. Images were obtained in PeakForce tapping mode at a scan rate of 0.501 Hz and a resolution of 512 pixels and were processed using NanoScope Analysis 1.5 software. The diameter of the NPs was measured to be $60 \pm 5 \text{ nm}$. See Figure S2 in the supporting material.

Both the zeta potential and hydrodynamic size of the NPs were measured with a Zetasizer Nano S90 (Malvern Instruments, Worcestershire, UK), using the following parameters: refractive index: 2.42, viscosity: 0.8872 cP, temperature: 25°C, medium: water, material absorbance: 0.01, refractive index of medium: 1.330, detection angle: 173°, wavelength 633

1 nm. The zeta potential and hydrodynamic size of the NPs were measured to be -13.9 ± 1.1
2 mV and 71.5 ± 0.1 nm respectively (see Fig. S3 in the supporting material), both of which
3 were measured in the phosphate buffer pH 7.4.

4 5 **2.3 CE and ICP-MS apparatus and conditions**

6 All the CE-ICP-MS experiments were carried out using the capillary electrophoresis
7 instrument CE7100, Agilent Technologies (Waldbronn, Germany). Separations were
8 performed in fused silica capillary with a length of 47 cm and an internal diameter of 50 μ m
9 (Molex, Lisle, IL, USA) by applying a separation voltage of 25 kV. The temperature of the
10 capillary cassette was set to 25 °C. Prior to their first use, the capillaries were initially
11 conditioned by being flushed with 0.1 mol.L⁻¹ NaOH for 20 minutes and then with deionized
12 water for another 20 minutes. Between each sample run, the capillaries were re-conditioned
13 by rinsing them with 0.1 mol.L⁻¹ NaOH (two minutes), deionized water (two minutes) and the
14 BGEs (four minutes). All the rinses were performed using a pressure drop of 935 mbar. The
15 sample was injected at 50 mbar for five seconds. Samples consisted of 100-fold diluted
16 dimethyl sulfoxide (which served as a marker of electroosmosis) and 50-fold diluted
17 Fe₂O₃@SiO₂ COOH NPs in deionized water.

18
19 The coupling of CE with a 7700x inductively coupled plasma mass spectrometer (Agilent
20 Technologies, Tokyo, Japan) equipped with an octopole reaction system was achieved with a
21 lab-made interface. The CE-ICP-MS interface was built using a cross-piece, a grounding
22 electrode, an inlet for sheath liquid (placed in the inlets of the cross-piece) and a MicroMist
23 concentric nebulizer. The sheath liquid (20 times diluted buffer solution without polymyxin
24 B) was introduced by a self-aspiration into the nebulizer inlet, where it was directly mixed
25 with the effluent from the CE capillary. The CE capillary goes through a cross-piece toward
26 the inlet of the MicroMist concentric nebulizer and ends approximately one millimeter away
27 from the beginning of the inner capillary.

28
29 Prior to each CE-ICP-MS hyphenation, the instrumental performance (such as the torch
30 position, the argon flow rate, etc.) was optimized with a standard solution of 1 μ g.L⁻¹ of Li, Y,
31 Ce, Tl, while a standard solution of Fe prepared in diluted buffer (100 μ g.L⁻¹) was used for the
32 fine tuning of the CE-ICP-MS (especially ion optic and the flow rate of He throughout the
33 collision cell) to achieve the maximum signal intensity for all measured iron isotopes. The
34 optimized ICP-MS instrumental conditions were as follows: RF power of 1550 W, plasma gas

flow rate of 14.95 L.min⁻¹, auxiliary gas flow rate of 0.9 L.min⁻¹, nebulizer gas flow rate of 1.1 L.min⁻¹, make up gas flow rate of 0.25 L.min⁻¹, He flow rate in collision cell of 3 mL.min⁻¹ and dwell time 100 ms for ¹²C, ³⁴S, ⁵⁴Fe, ⁵⁶Fe and ⁵⁷Fe isotopes (despite the identical results for all iron isotopes, the most abundant ⁵⁶Fe isotope was used for the mobility evaluation; see Fig. S4 in the supporting material). In addition, the signal of ³⁴S isotope was used not only as a marker of electroosmotic flow, but also to monitor the stability of the CE-ICP-MS connection based on the analysis of the sulfur throughout the CE-ICP-MS analysis. The ratio of ⁵⁶Fe and ³⁴S isotopes peak area did not exceed 1.2 (SD 0.2, n = 16) in the whole concentration range of polymyxin B showing excellent stability of the CE-ICP-MS connection.

2.4 ACE theory

In the ACE mode, the analyte A is injected and migrates through the electrolyte containing the ligand L. The effective mobility of the analyte in equilibrium with the ligand μ_A^{eff} is the average of the actual mobility of both the free μ_A^0 and bound μ_{AL}^0 forms of the analyte, weighted by the molar fraction. If combined with eq. 2, the effective mobility of the analyte in equilibrium with the ligand could be expressed as follows:

$$\mu_A^{\text{eff}} = \frac{1}{1+K_b[L]} \mu_A^0 + \frac{K_b[L]}{1+K_b[L]} \mu_{AL}^0 \quad (3)$$

In order to apply eq. 3, the equilibrium ligand concentration should be constant during the separation and should be known. It is common practice to substitute the equilibrium ligand concentration with the free ligand concentration, supposing that the analyte concentration does not overtake the ligand concentration. It is recommended that the ligand concentration should be higher than the analyte concentration of one order of magnitude [50].

Generally, the treatment of the relation between analyte effective mobilities and ligand concentrations is based on non-linear or linear regression [51, 52]. In our case, the x-reciprocal method, which is sometimes called the Scatchard plot, was used to treat the data. The equation of the Scatchard plot could be written as follows:

$$\frac{\mu_A^{\text{eff}} - \mu_A^0}{[L]} = -K_b(\mu_A^{\text{eff}} - \mu_A^0) + nK_b(\mu_{AL}^0 - \mu_A^0) \quad (4)$$

Here, n is the stoichiometric ratio between the analyte and the ligand. This linearization procedure used to be one of the most common linearization methods for cases where the determination of binding constants is performed with various techniques [51, 53].

3 Results and discussion

In order to prove that the $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH NPs can be used for capturing polymyxin B in a microdevice for testing bacterial resistance, we studied the strength of the interaction by using the CE-ICP-MS connection. CE-ICP-MS was used instead of CE-DAD because it allows detecting isotopes and therefore it allows correct determination of migration times of interacting species; see an example of CE-DAD profiles in Fig. S5 in the supporting material. A typical ACE setup was used; polymyxin B was added to the running 25 mM phosphate buffer at a physiological pH of 7.4 and the mobilities of NPs were studied in detail. The choice of running buffer composition and pH was in accordance with the subsequent use of the setup in the proposed microdevice. The concentration of polymyxin B varied from 0 to $250 \times 10^{-7} \text{ mol.L}^{-1}$. Higher concentrations of polymyxin B were not studied because aggregation of NPs was observed ($> 350 \times 10^{-7} \text{ mol.L}^{-1}$). Fig. 1 shows an example of the CE-ICP-MS analysis of the $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH NPs with different polymyxin B concentrations. Isotopes ^{34}S (from DMSO) and ^{56}Fe (from NPs) were used for calculating the NP mobilities. The dependence of effective mobilities of NPs on concentrations of polymyxin B (Fig. 2A) shows two distinct interaction regions with concentrations of polymyxin B of $1\text{--}50 \times 10^{-7} \text{ mol.L}^{-1}$ and $100\text{--}250 \times 10^{-7} \text{ mol.L}^{-1}$. The transitional concentrations region ($50\text{--}100 \times 10^{-7} \text{ mol.L}^{-1}$) represents the area where the interaction mechanism is probably changing.

Interestingly, the two interaction regions also differed with respect to the peak shape of NPs. While the NPs formed quite sharp peaks in the BGEs with low polymyxin B concentrations, they created broad zones in high polymyxin B concentrations (see also Fig. 1). In order to be sure that these broad zones corresponded to NPs interacting with polymyxin B, pressure-assisted CE-ICP-MS was performed. The NPs were analyzed in the phosphate buffer with an addition of $300 \times 10^{-7} \text{ mol.L}^{-1}$ polymyxin B under the pressure drop of 50 mbar. The ^{12}C peak appeared after approximately 2 minutes (Fig. 3), which corresponds to the migration of NPs (^{56}Fe), represents the response of polymyxin B when interacting with these NPs. This observation shows the unique role of element specific ICP-MS detection, allowing for the detailed study of polymyxin B interactions with NPs under physiological conditions. On the other hand, the “carbon” content corresponding to the injected amount of $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH

1 NPs was too low to be distinguished from the background signal of the running buffer with
2 increasing concentrations of polymyxin B. Furthermore, no ^{12}C peak of NPs was detected for
3 0 mol.L^{-1} of polymyxin B.

4
5 Finally, the dependencies of NP mobilities on polymyxin B concentration were linearized
6 according to the Scatchard equation (see the experimental section and Fig. 2B). Again, the
7 two interaction regions for low and high polymyxin B concentrations were observed (Tab. 1).
8 The first region (low polymyxin B concentrations) is represented with quite high interaction
9 constant and with the stoichiometry (0.7) where a less number of polymyxin B molecules
10 interact with one nanoparticle. The second region (high polymyxin B concentrations), on the
11 other hand, acts with quite low interaction constant but with the stoichiometry (3.5) where
12 more polymyxin B molecules interact with the nanoparticle. In this second region, the
13 significant decrease of surface charge of $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH NPs can be also supposed due
14 to their interaction with more molecules of positively charged polymyxin B (pK values are
15 higher than nine [54]). This is also experimentally proved by the decrease of NPs' mobility
16 (Fig. 2A) and increase of NPs' peak width (modification of NPs leads to the increase of peak
17 width [55]). Interestingly, the effect of polymyxin B concentration on $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH
18 NPs is not gradual but it has a drop forming the two interacting regions but this seems to be
19 quite common with NPs [56, 57].

21 4 Conclusions

22 In this work, interactions between $\text{Fe}_2\text{O}_3@\text{SiO}_2$ COOH NPs and polymyxin B sulfate were
23 studied using CE-ICP-MS to prove that these NPs can be used for capturing polymyxin B in a
24 microdevice to test bacterial resistance. The precise analysis of the interactions was possible
25 due to the analysis of different isotopes using ICP-MS. ^{54}Fe , ^{56}Fe , ^{57}Fe isotopes were used for
26 detection of NPs, ^{34}S isotope for the electroosmosis, and ^{12}C isotope reflected the interaction
27 of polymyxin B with the NPs. The analysis of the interaction plot showed two interaction
28 regions with a stoichiometry of 0.7 and 3.5. This can be explained by the drop decrease of
29 electrostatic repulsion between NPs and polymyxin B with increasing polymyxin B
30 concentration. Moreover, in the view of the microdevice for testing the bacterial resistance,
31 the optimization of polymyxin B concentration is necessary. The successful capture of
32 polymyxin B will only happen with low polymyxin B concentrations, where the higher
33 interaction constant was found. Here, the NPs forms also quite sharp CE zone representing
34 their stable dispersion. This is contrary to the fact that the “non-stable” dispersion of NPs

(larger and “hairy” peaks) would probably be easily stacked in the channel with the application of a magnetic field. However, the power of the interactions in this second region of polymyxin B concentrations is not high enough to successfully capture polymyxin B.

Figure captions

Figure 1: An example of the CE-ICP-MS analysis of the $\text{Fe}_2\text{O}_3@\text{COOH}$ NPs with different polymyxin B concentrations

BGE: 25 mM phosphate buffer pH 7.4, separation at 25 kV

Figure 2: A, The dependence of NPs effective mobilities on concentration of polymyxin B, B, Scatchard plot

BGE: 25 mM phosphate buffer pH 7.4; SD values are given in parenthesis ($n = 5$); for the explanation, see the theory, part 2.4

Figure 3: Pressure-assisted ACE-ICP-MS for confirmation of interaction of NPs with polymyxin B

BGE: 25 mM phosphate buffer pH 7.4, separation at 25 kV, pressure of 50 mbar, polymyxin B concentration: $300 \times 10^{-7} \text{ mol.L}^{-1}$

Figure 1: An example of the CE-ICP-MS analysis of the $\text{Fe}_2\text{O}_3@\text{COOH}$ NPs with different polymyxin B concentrations
 BGE: 25 mM phosphate buffer pH 7.4, separation at 25 kV

Figure 2: A, The dependence of NPs effective mobilities on concentration of polymyxin B, B, Scatchard plot

BGE: 25 mM phosphate buffer pH 7.4; SD values are given in parenthesis ($n = 5$); for the explanation, see the theory, part 2.4

Figure 3: Pressure-assisted ACE-ICP-MS for confirmation of interaction of NPs with polymyxin B
BGE: 25 mM phosphate buffer pH 7.4, separation at 25 kV, pressure of 50 mbar, polymyxin B concentration: $300 \times 10^{-7} \text{ mol.L}^{-1}$

1 **Table 1: Interaction and stoichiometry results**

2

Concentration of polymyxin B	K_b (M^{-1})*	n*
$1 - 50 \times 10^{-7} \text{ mol.L}^{-1}$	$14.9 (4.4) \times 10^6$	0.7 (0.3)
$100 - 250 \times 10^{-7} \text{ mol.L}^{-1}$	$16.0 (2.2) \times 10^3$	3.5 (0.5)

3 *standard deviations are displayed in parenthesis
