Abstract

Herein, we demonstrate the potential of ultrabright fluorescent silica-coated organic nanocrystals for two-photon *in vivo* imaging. These unique nanoparticles (NPs) containing a crystalline core of small push-pull dipolar dye are specifically designed to exhibit two-photon absorption for

fluorescence imaging. The NPs can be easily functionalized using click chemistry in pure water, with preservation of the organic core. A novel small-volume DLS technique was used to evaluate the effect of PEGylation on the colloidal stability of the NPs in complex media containing salts and proteins, mimicking the composition of blood serum. The potential of these bright red-emitting NPs for two-photon fluorescence imaging is demonstrated both *in vitro* and *in vivo*.

Keywords

Nanoparticles; bio-imaging; two-photon absorption; dynamic light scattering; colloidal stabilization

Introduction

Optical imaging techniques offer several advantages for early diagnosis of tumors and imaging-guided therapy compared to alternative approaches, such as high sensitivity, high spatial resolution, high signal to noise ratio in the near infrared spectral region and the use of low concentrations of contrast agent,¹⁻⁵. However, optical imaging has been primarily limited to dermal and ocular applications, due to autofluorescence, light scattering and attenuation by tissues and the absorption of light by hemoglobin, lipids and water, leading to low penetration depths.^{6,7} Optical imaging in the near infrared (NIR) region (650 nm – 1700 nm), where light scattering and photon absorption are minimal, enables deeper tissue penetration and improved signal to noise ratios.^{6,7}

Nonlinear optics and the development of multiphoton microscopy have further helped to achieve deeper tissue penetration, thereby expanding the scope of *in vivo* optical approaches for deep tissue imaging. Two-photon microscopy, which exploits the simultaneous absorption of two photons, each with half the energy (and twice the wavelength) of the corresponding single photon transition, to excite the fluorophore, enables deeper tissue penetration as it typically shifts the excitation wavelength from the visible to the biological transparency window in the NIR range. Additionally,

photodamage is greatly minimized due to the use of lower energy photons and confinement of fluorescence emission to a diffraction-limited spot.⁸ This makes two-photon microscopy ideal for high-resolution (μm -scale), deep-tissue, real-time imaging and tracking of dynamic processes in cell biology.⁶

In order to realize deep-tissue optical imaging, it is crucial to develop tracers that not only exhibit the required photophysical properties (such as two-photon absorption and a fluorescence emission in the NIR), but also good biocompatibility, high sensitivity and specificity. Many organic dyes which show two-photon absorption are hydrophobic, leading to molecular aggregation in aqueous media and associated fluorescence quenching, which in turn limits their use as fluorescent probes for imaging.

The development of new types of fluorophores relying on aggregation-induced emission (AIE) has overcome the problem of aggregation-induced quenching. In particular, organic dyes that form J-aggregates have shown great potential for use in bio-imaging. J-aggregation refers to the self-assembly of molecules in a head-to-tail arrangement, resulting in delocalization of the π -electrons over the self-assembled molecular aggregate, which in turn leads to constructive coupling of the excited state transition dipoles.^{9,10} This results in several interesting photophysical characteristics, such as red-shifted absorption and emission spectra, narrow absorption and emission bands, high absorption coefficients and good quantum yields.^{9–11} Several organic dyes designed to form J-aggregates have been reported in the literature, such as perylene bisimide derivatives¹², pyrrolopyrrole cyanine derivatives¹³, heptamethine cyanine dyes^{10,11,14} and porphyrin-based dyes^{15–17}. These chromophores are often complexed with polymers or encapsulated in nanoparticles (NPs) to impart stability and enhance their functionality. J-aggregates based on heptamethine cyanine dyes complexed with amphiphilic polymers to form stabilized polymeric micelles have

been reported by Liu and coworkers.^{11,14} These polymer-stabilized J-aggregates have been further complexed with iron oxide nanoparticles¹¹ and anticancer drugs¹⁴ for photothermal and combination cancer therapy, respectively. Polymeric-micelle-stabilized J-aggregates of pyrrolopyrrole cyanine¹³ for *in vivo* imaging and squaraine⁵ for image guided photothermal therapy have also been reported.

Organic dyes exhibiting AIE have also been encapsulated in protein nanoparticles^{18,19} to enhance uptake by cancer cells and enable two-photon *in vivo* imaging. Silica-based NPs are also interesting options for the encapsulation of AIE based dyes, due to the availability of well-established synthesis protocols for controlling their size, their low intrinsic toxicity and ease of surface modification to increase their colloidal stability.^{20,21} In addition, the inert silica matrix can shield encapsulated dye molecules from the external environment, providing stability, optical transparency, and biocompatibility.^{21,22} Furthermore, the silicate matrix can be readily functionalized through silica surface chemistry, thereby providing an efficient strategy for the encapsulation of hydrophobic nanocrystals to obtain water-soluble nanomaterials.^{23–25} AIE based dyes have also been incorporated into silica NPs for bio-imaging.^{26–29}

J-aggregates of a heptamethine dye have been prepared inside hollow mesoporous silica nanoparticles for NIR imaging by Sletten and coworkers.¹⁰ The silica nanoparticles have been shown to stabilize J-aggregates and facilitate high resolution *in vivo* imaging in mice.¹⁰ Prasad and coworkers have developed organically-modified silica (ORMOSIL) NPs loaded with a high concentration of AIE-based dyes for two-photon fluorescence imaging³⁰ and photodynamic therapy when co-encapsulated with a photosensitizing drug.³¹

Encapsulation of organic crystal-state emitters in sol-gel matrices is an efficient strategy to produce bright nanotracers for bio-imaging applications.^{32–36} As described in our previous work,³⁶ fluorescent organic@silicate core-shell nanoparticles (NPs) containing a crystalline organic core

surrounded by a silicate shell, with a high loading of dyes (30-40 wt %) are promising for bio-imaging applications. These recently-described core-shell NPs, which comprise a nanocrystalline organic-dye core (*ca* 40-50 nm) surrounded by a silicate shell, are prepared by a novel spray-drying technique which combines sol-gel chemistry and crystallization.^{32,36–38} The organic dyes used in the core-shell NPs are based on the D- π -A dipolar structure and are specifically designed to exhibit two-photon absorption in the crystal state.³⁹ The permanent dipole moment associated with such structures results in strong dipole-dipole interactions, which in turn can induce specific organization and orientation of the molecules in the solid state.³⁸ These core-shell NPs show fluorescence emission in the red, close to the biological transparency window, making them interesting candidates for deep-tissue imaging using two-photon microscopy.

In this study, we evaluate the potential of our novel organic@silicate core-shell NPs for two-photon *in vivo* fluorescence imaging. The CuAAC (Copper Catalyzed Azide to Alkyne Cycloaddition) click reaction⁴⁰ was used to graft PEG chains onto the core-shell NPs to enhance their colloidal stability and “stealth” in blood by minimizing protein adsorption and opsonization.^{41–47} Classical DLS experiments coupled with small-volume DLS (confocal geometry) was used to characterize the colloidal stability of the NPs in different biological media with increasing complexity, starting with simulated body fluid (SBF) and various plasma proteins in increasing concentrations. Finally, we present, two-photon fluorescence properties in solution to demonstrate the potential of these NPs for two-photon fluorescence imaging both *in vitro* and *in vivo*.

Experimental section

Details of materials, reagents and characterization techniques are given in the supporting information

Synthesis of core-shell NPs with clickable functions

Figure 1 schematically summarizes the preparation of nanoparticles by spray-drying and the PEGylation step subsequently used to obtain stable colloidal suspensions.

Figure 1 : Preparation of nanoparticles

The sols and the core-shell NPs (**NP-I-N₃**) were prepared according to the published protocol³⁶ using a 2:1 molar ratio of tetramethoxysilane (TMOS) and 1,2-bis(trimethoxysilyl)ethane (TMSE), with 3% AzPTES with respect to Si and dilute aqueous HCl (1 M HCl) in THF. Briefly, dilute HCl was added to the silicate precursors, previously dispersed in 5 mL of THF, under vigorous stirring, followed by aging for 3 days at 60 °C. Finally, additional THF was added after aging to reach a final volume of 60 mL. The as-prepared sols were stored at 4 °C. The dye was dissolved in the sol just before nebulization and spray-drying and the sol was nebulized under the conditions described in our previous work, yielding organic nanocrystals covered with a silicate layer.³⁶ The crystalline nature of the organic core was ascertained by electron diffraction and by PXRD (Figure S1). A controlled partial dissolution of the silicate shell of the sprayed-dried NPs was performed by sonicating the NPs in water (60 mL) for 20 minutes in an ultrasonic bath (150 W), before increasing

the solution pH to 12 by adding 1 M NaOH. The resulting suspension was stirred for 24 h in a closed bottle. The NP suspension was then subjected to centrifugation for 5 minutes at 5000 rpm and the supernatant was filtered using 5 μm , 1.2 μm and 0.8 μm syringe filters, to remove large aggregates. This step was followed by neutralization of the NP suspension to pH 7.4 by the dropwise addition of 1 M HCl. The resulting NP suspensions were used for fluorescence spectroscopy measurements. The pH of the neutralized core-shell NPs for click functionalization was further stabilized using 0.133 M phosphate buffer by adding a volume corresponding to 10% of the volume of the NP suspension.

CuAAC functionalization of core-shell NPs

The treated core-shell NPs were functionalized using the CuAAC click reaction, following the protocol described by Moitra et al.⁴⁸ Five equivalents of propargyl-PEG 5000-OMe for each equivalent of AzPTES were first weighed into a bottle in which the treated NP suspension was added under constant stirring. One equivalent each of tris-(3-hydroxypropyltriazolylmethyl)amine (THPTA) and of the pre-catalyst, copper sulphate ($\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$), were then added to this solution. Argon was bubbled into the colloidal suspension for a few minutes to remove any traces of oxygen before the addition of four equivalents of sodium ascorbate. More Ar was bubbled in the suspension and the bottle was then closed and kept under constant stirring at room temperature for 24 hours. Purification of the functionalized NPs (**NP-I-PEG**) was performed by dialyzing the NP suspension (10 mL in Pur-A-Lyzer tubes with 3.5 kDa pore size) against 2.5 L of 0.0133 M PB for two days. The purified NP suspensions were concentrated using Vivaspin 2 (2 mL) concentrators. Centrifugation was performed at 3000 rpm for 3 minutes on volumes of 2 mL. Successive centrifugations were performed to increase the concentration of particles in suspension.

Steady-state spectroscopic experiments under resonant one-photon absorption conditions

The two-photon excitation cross-section measurements were performed by detecting the two-photon excitation-induced fluorescence (TPEF) of the NPs compared to the signal of a pH 13 aqueous solution of fluorescein ($c=10^{-5}$ mol/L) used as a standard.^{49,50} The experimental setup is based on a femtosecond Ti:Sapphire laser (Chameleon Ultra I, Coherent, 80 MHz pulse repetition rate, 140 fs pulse duration) allowing for tunable excitation between 700 and 1040 nm. The laser intensity was adjusted by using a continuously variable neutral density filter to ensure constant excitation power in the tuning range. The laser power was monitored by a NIST traceable thermal detector (S405C, Thorlabs). The laser beam was focused into the 10×10 mm quartz (QZS) sample cell by a 100 mm focal length lens. The fluorescence signal was detected at 90° to the excitation beam. The cell position was adjusted so that the optical path of both the excitation beam and the fluorescence emission was minimized in the cell, thus reducing experimental artefacts such as inner-filter effects, scattering and solvent absorption. The emitted fluorescence was filtered using a low-pass interference filter and delivered to a fiber optic spectrometer (AvaSpec-EVO, Avantes).

In vitro and in vivo assays

For *in vitro* experiments, MCF-7 human breast cancer cells were used (purchased from ATCC) and cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum and $50 \mu\text{g mL}^{-1}$ gentamycin and maintained under a humidified atmosphere at 37°C containing 5% CO_2 (incubator). Cytotoxic studies were realized by seeding MCF-7 on 96-well plates (2000 cells/well). The day after seeding, cells were incubated with increasing concentrations of **NP-I-PEG** (from 0.05 to $50 \mu\text{g mL}^{-1}$). One day after, the plates intended for "light cytotoxicity" study were exposed during 4 h at the sunlight, then they were replaced in the incubator in the dark for the remaining 48 h. The plates "dark cytotoxicity" stayed in the incubator 72 h without interruption. At the end of the 3 days, a MTT assay was performed to determine the cell viability. Briefly, cells were incubated for 4 h with 0.5 mg mL^{-1} of MTT (3-(4,5- dimethylthiazol-2-yl)-2,5-

diphenyltetrazolium bromide; Promega) in culture medium. The MTT/medium solution was then removed and the precipitated crystals were dissolved in EtOH/ DMSO (v/v). The solution absorbance was read at 540 nm in a microplate reader. All values are reported in relation to the control values (without any treatment) which are considered as 100% living cells.

For fluorescence imaging on living cells, MCF-7 cells were seeded in glass bottom dishes (World Precision Instrument, Stevenage, UK), one day prior to commencing the experiment, at a density of 10^6 cells.cm⁻². Cells were then washed once and incubated in 1 mL culture medium with or without **NP-I-PEG** at a concentration of 10 or 25 $\mu\text{g mL}^{-1}$ for 24 h. Two hours before the end of the incubation, cells were loaded with LysoTracker green (1 μM , Molecular Probes, Life technologies, Oregon, USA); 15 minutes before the end of incubation, cells were loaded with Hoechst 33342 (10 $\mu\text{g mL}^{-1}$, Invitrogen, Cergy Pontoise, France) for nuclear staining, or with green CellMask (5 $\mu\text{g mL}^{-1}$, Invitrogen, Cergy Pontoise, France) for membrane staining. Before microscope observation, cells were gently washed with cell culture medium and scanned with a LSM 780 LIVE confocal microscope (Carl Zeiss, Le Pecq, France), at 450 nm (continuous) or 900 nm using the Chameleon (pulsed) laser for **NP-I-PEG** visualization. Samples were excited at 561 nm for membranes, at 760 nm for nuclei and at 488 nm for lysosomes.

All images were performed with a high magnification (63 $\times$ /1.4 OIL DIC Plan-Apo).

For mice studies, all experimental procedures were carried out in accordance with European regulations for animal use and were authorized by the local Ethics Committees (CEEA-55/CETEA-2015-0038) and the French Ministry of National Education and Research (APAFIS# DR2017-58).

For two-photon *in vivo* imaging, 8-week-old CX3CR1^{eGFP/+} mice, expressing GFP only in microglia in the central nervous system (SNC), were used. For transcranial imaging, a thinned-skull cortical window preparation was performed over the somatosensory cortex, where the skull

was thinned to 20-30 μm . Mice were deeply anesthetized with isoflurane (3-4%, Isovet, Piramal Healthcare, UK Ltd.) and mounted in a stereotaxic apparatus (D. Kopf Instruments). Carprofen (5 mg/kg s.c.) was injected at the beginning of the surgery to reduce post-surgical pain and inflammation. After the skull was exposed, a thin custom-made metal implant was glued allowing the area over the somatosensory cortex to be delimited. The skull was then carefully thinned using a high-speed dental drill. To avoid heat-induced damage, drilling was repeatedly interrupted and cold sterile saline was applied. When a 20 to 30 μm skull thickness was reached, a thin layer of cyanoacrylate glue was applied and a cover glass was placed on top of the thinned skull.

For *in vivo* imaging sessions, mice were anesthetized with a mixture of ketamine (100 mg/kg) and xylazine (10 mg/kg). Their body temperature was maintained at 37 °C using a heating pad. A retro-orbital injection of 200 μL of a NP solution at a concentration of 80 $\mu\text{g/mL}$ was performed while the mouse was deeply anesthetized. Two-photon microscopy observations were performed on a Bruker Ultima microscope (Insight 3X laser, Spectra Physics), equipped with a 20 $\times$ water-immersion objective (0.95 N.A. Olympus). Green (CX3CR1^{eGFP/+} cells) and red (NPs) fluorescence were separated by a 560 nm dichroic mirror coupled to 525/50 nm and 650/40 emission filters. Images were acquired every 0.9 seconds over an area of 200 $\times$ 200 μm^2 and a resolution of 521 $\times$ 521 pixels, and laser power was maintained below 30 mW. The open source software packages *ImageJ* and *Icy*, created by BioImage Analysis Lab, Institut Pasteur (France; <http://icy.bioimageanalysis.org/>) were used for image treatment, while drift correction was applied using custom-written *Matlab* software to correct image drift during acquisition.

Results and discussion

Due to the presence of organic nanocrystals at the core of the NPs, surface functionalization had to be performed in aqueous solution to minimize dissolution of the hydrophobic core. Our previous protocol³⁶ was thus adapted to incorporate an azide functionality within the NPs during sol-gel synthesis (figure 1),^{48,51} for subsequent functionalization with alkyne-modified moieties via the CuAAC reaction in pure water. In addition to TMOS (2 eq.) and TMSE (1 eq.), 3 mol% of (3-azidopropyl)triethoxysilane (AzPTES) was added to the starting sol. Using dye **I**, the morphology and size distribution of the NPs (**NP-I-N₃**) obtained (FESEM image, Figure 2) were unaltered after the introduction of this new silicate precursor into the sol (Figure S2).

Figure 2 : (a) Structure of the dye (E)-2-(benzo[d]thiazol-2-yl)-3-(4-diphenylamino)phenylacrylonitrile . (b) FESEM imaging of as-synthesized **NP-I-N₃**. (c) **NP-I-PEG** after size selection and PEGylation (right).

Fourier transform infrared spectroscopy (FTIR) confirmed the presence of a high loading of dye (30-40 wt% as previously determined by TGA³⁶) and the azide groups within the NPs (supporting information, Figure S3). Indeed, the bands corresponding to --CN (2210 cm^{-1}) and C=C (1573 cm^{-1}) from the dye are clearly visible in the spectrum of **NP-I-N₃**, and absent in dye-free NPs. The integrity of the encapsulated dye molecule after synthesis was demonstrated by absorption and fluorescence spectroscopy after dissolving the **NP-I-N₃** NPs in ethanol.

To disperse the dry NP powder obtained by spray-drying, a partial dissolution of the silicate shell with sodium hydroxide at pH 12 was performed for 24 h in order to separate the chemically aggregated NPs and impart a strongly negative ζ potential. After this treatment, the suspension was

centrifuged to sediment the largest particles and aggregates, then the supernatant containing the desired NPs was filtered using 5 μm to 0.8 μm cellulose acetate membranes and finally neutralized to pH 7.5.

The suspension of NPs as prepared in pure water was characterized by DLS measurements. The auto-correlation functions of the measured intensities were derived and fitted to determine the average size of the NPs and the width of their size distribution. The latter is shown in Figure S4-a. in the supporting information, as a function of the number of NPs and as a function of their scattered intensities; the latter favors the largest NPs, since scattering intensity increases with increasing particle size. These suspensions were stable for several hours, although the subsequent addition of sodium chloride up to 0.9 wt %, which corresponds to blood salinity, had a strong negative impact on the colloidal stability. This effect was monitored by DLS measurements, performed every minute over two hours, that showed a progressive increase of the average size of the scattering species as a function of time (SI, Figure S4-b). This reflects the salt-induced aggregation of NPs, which was further confirmed by observing the NP sedimentation on a longer time scale, namely during fluorescence spectroscopy experiments performed over 5 hours (SI, Figure S4-b). This colloidal instability in saline environments makes it necessary to functionalize the surface of the NPs.

Accordingly, we covalently grafted polyethylene glycol ($M_n = 5000$) onto the organosilica surface of the core-shell NPs using the CuAAC click reaction of **NP-I-N₃** with propargyl-PEG-OMe (Figure 3).

Figure 3 : CuAAC click functionalization of NPs

The comparison of the FTIR spectra before and after functionalisation (SI - Figure S3) demonstrates the success of the CuAAC reaction, with a strong decrease in the azide band (N=N=N stretch) intensity at 2100 cm^{-1} and the appearance of bands corresponding to the C-H bonds of the PEG chains in the range $2800\text{-}2900\text{ cm}^{-1}$. The efficiency of PEG grafting is also shown by the decrease in ζ potential at pH 7.4 from -40 mV before functionalization to around -10 mV after pegylation.

After centrifugation, the **NP-I-PEG** colloidal suspensions ($80\text{ }\mu\text{g/mL}$) in pure water were again characterized by DLS measurements. The analyses of the auto-correlation functions lead to an intensity-weighted size distribution centred at *ca* 170 nm (figure S 6 (a)) and a width corresponding to sizes ranging from 100 to 300 nm , in agreement with the SEM micrographs showing NPs of about 100 nm and small aggregates (Figure 2).

To further characterize the suspensions, DLS and FCS experiments under a confocal microscope were also performed.⁵² The experiments involve measuring the elastic (for DLS) or inelastic scattering (here fluorescence for FCS) of the NPs as their Brownian motion brings them to diffuse through a small observation volume where they are illuminated and scatter light. The measured

intensities exhibit temporal fluctuations related to an increase (or decrease) of signal each time a NP enters (or leaves) the confocal volume. Consequently, the amplitudes and duration of these fluctuations are related to the mean number, $\langle N \rangle$, of NPs, and to their residence time, τ_D , respectively, within the observation volume. Both parameters can be obtained by adjusting their values through fitting of the intensity auto-correlation function, $ACF = G(t) - 1$, where $G(t) = \frac{\langle I(\tau)I(t+\tau) \rangle}{\langle I(\tau) \rangle^2}$. The size and the concentration of the NPs are further obtained from the experimental determination of $\langle N \rangle$ and τ_D . The detailed procedure is given in supporting information.

A series of ten DLS experiments were performed with this setup, leading to a slightly different ACF for each measurement due to the dispersion of the NPs and to the fact that only a few of them are measured simultaneously, in contrast to the conventional DLS equipment. An averaged ACF is presented in Figure 4-a together with the calculated one using $G(0) = 21.8$ and $\tau_D = 3$ ms. Knowing the confocal volume $V_c = 0.7 \text{ } \mu\text{m}^3$ and its radius $r_0 = 190 \pm 30$ nm from calibration measurements, we obtain a mean concentration $C = 2.1 \times 10^{10}$ p/mL and a mean hydrodynamic diameter $d_H = 160 \pm 30$ nm. The different ACFs present characteristic residence times ranging from 2.5 to 4 ms, which correspond to hydrodynamic diameters ranging from 80 to 300 nm, and $\langle N \rangle$ value ranging from 0.012 to 0.024, corresponding to a concentration $C = 2.5 \pm 0.8 \times 10^{10}$ p/mL. These results are in full agreement with the NP sizes obtained from the commercial DLS, and with the initial concentration of 80 $\mu\text{g/mL}$ corresponding to a concentration of 2×10^{10} p/mL when considering NPs of 170 nm in diameter and of density of 1.5.

Figure 4 : (a) DLS experimental ACF averaged over ten measurements (dots) and calculated fit (line) with $G(0) = 21.8$ and $\tau_D = 3$ ms and (b) FCS experimental ACF (dots) averaged over ten measurements and calculated one (line) with $G(0) = 2.4$ and $\tau_D = 5$ ms.

FCS measurements were analysed using exactly the same experimental procedure. As can be seen in Figure 4-b, the value $G(0) = 2.4$ is significantly smaller than that of the DLS ACFs due to a much weaker signal-to-noise ratio. However, taking the latter into account ($c^2 \sim 0.055$ and $\langle N \rangle = c^2/G(0)$, see SI), a concentration $C = 3.3 \times 10^{10}$ p/mL is obtained, which is in accordance with the concentration measured in DLS. This similarity indicates that all the NPs emit a fluorescence signal, hence confirming the presence of the fluorescent crystal within the core/shell NPs. The characteristic residence time, $\tau_D = 5$ ms, is larger than the values obtained from DLS. This is attributed to the weakness of the fluorescence signal that favours the detection of the largest NPs and to a possible retardation of the NPs due to weak optical trapping within the confocal volume resulting from the much larger incident power used as compared to that in DLS.⁵³

Blood is a complex medium containing mainly high amounts of salts (ionic strength around 0.15 M), proteins and cells. To predict the colloidal stability in blood, we undertook a series of DLS analyses in environments of increasing chemical complexity, approaching step by step the plasma composition.

The first step was to check the stability of the colloidal solution of PEGylated NPs (**NP-I-PEG**) in the presence of a salty medium and in the presence an ionic environment simulating that of blood at 37°C. DLS measurements were performed in solutions of the functionalized **NP-I-PEG** in pure water and at 25 °C and were compared to those obtained at 37 °C in pure water, with 0.9 wt% NaCl, for the salty medium, and with simulated body fluid (SBF) which mimics blood's ionic composition (Table S1). The size distributions of the NPs obtained from these DLS measurements are presented in supporting information (Figure S6). Neither the temperature, the salty medium nor the SBF influences the size distribution of the NPs, which are similar to that of the **NP-I-PEG** in pure water and at 25°C. Moreover, in all situations, the functionalized **NP-I-PEG** were stable with a mean size lower than 200 nm, in contrast to the unfunctionalized **NP-I-N₃**.

The colloidal stability of the NPs was then tested in the presence of plasma proteins at 37 °C, at least 15 minutes after addition. The latter constitute a major fraction of blood, with serum albumins constituting 55% of the total amount of blood plasma proteins, globulins constituting 38% and the remaining 7% constituted mainly by fibrinogen. It is now well documented that the interaction of NPs with those proteins lead to the formation of a protein corona⁵⁴, which may lead to aggregation or recognition by the macrophages. It is therefore essential to check the colloidal stability and possible aggregation of **NP-I-PEG** in the presence of plasma proteins. Incremental experiments were performed: (i) the interaction of the NPs with bovine serum albumin (BSA) as a model albumin was first probed; (ii) the effect of the second most abundant protein in the blood plasma,

namely γ -globulin, was then investigated; and finally, (iii) the colloidal stability of the functionalized NPs was investigated in an environment composed of a combination of the individually tested proteins (SBF, BSA and γ -globulin). As previously, the colloidal stability was investigated by DLS measurement performed at 37°C. During the first step, an increasing amount of BSA in SBF, ranging from 6 to 60 mg/mL, was added to the **NP-I-PEG** suspensions. The limiting concentration of 60 mg/mL corresponds to the maximum concentration encountered in blood. DLS measurements were also performed on a pure BSA solution as a reference. Figure 5-a presents the normalized ACFs of the BSA and of the NPs in SBF together with their fit calculated for characteristic time decays of 18 μ s for BSA and 910 μ s that corresponds to hydrodynamic diameters of 8.4 nm and 200 nm, respectively (which are the expected values). As the characteristic residence time of the BSA and that of the NPs are very different, their respective contribution to the ACF are not correlated and therefore simply sum to yield the final ACF. At short times, the time decay due to the BSA becomes more visible as its concentration increases. At longer time, and at low concentrations in BSA (6 and 15 mg/mL), the ACFs are very similar to that of the NPs only in the presence of SBF, indicating the stability of the colloidal solutions. At higher BSA concentrations (30 and 60 mg/mL), a slight shift of the ACFs is observed at longer times, consistent with an increase in the polydispersity of the solutions. To obtain more quantitative results, the ACFs were fitted and the NPs size distributions were obtained. The latter are displayed in Figures 5-b,c, both as number- and intensity-weighted distributions. At low concentrations of BSA (6-15 mg/mL), the size distributions are very similar to those obtained for the NPs in pure water, confirming that no aggregation occurred. At higher concentrations, a peak at 8 nm appears in the number-weighted distribution, while that of the NPs disappears. This corresponds to the observation of the diffusion of the albumin molecules whose concentration becomes important.

The situation is different in the case of the intensity-weighted distributions, as the latter favors the larger objects due to their larger contribution to the observed signal. A slight aggregation was observed only at the highest concentration of BSA (60 mg/mL), resulting in a size increase from 220 nm to ~260 nm, while only a slight broadening of the distribution is observed for the 30 mg/mL concentration in BSA. However, the observation of aggregation at a BSA concentration of 60 mg/mL is not problematic, as this concentration is higher than the upper limit of the normal albumin concentration in the body. The stability of the functionalized NPs suspension under nominal conditions is therefore confirmed.

Figure 5 : (a) Normalized autocorrelation data corresponding to *NP-I-PEG* in SBF with BSA at a concentration of 0 mg/mL (orange), 6mg/mL (black), 15 mg/mL (red), 30 mg/mL (blue) and 60 mg/mL (pink); of pure BSA in PBS (green). Fits of the green and orange plots (black) give a characteristic time of 18 ms for BSA and 910 ms for the *NP-I-PEG*. (b) Number and (c) Intensity distributions of *NP-I-PEG* in SBF at 37 °C with the different concentrations of BSA.

The effect of the second most abundant protein in blood plasma, γ -globulins, which are constituents of the immune system, was investigated next. DLS measurements were performed on a solution containing only γ -globulin molecules and on solutions of NPs in SBF with γ -globulin at a concentration of 10, 25 and 45 mg/mL. The measured ACFs are displayed in SI (Figure S7-a), together with that of the NPs in SBF. The contribution of the γ -globulin in ACFs appears as a time decay of 52 μ s (Figure S7-a), which corresponds to a diameter of 11.5 nm for the equivalent spherical molecule. As for BSA, this scattering is expected to contribute to that of the NPs when

γ -globulin is added to the solution without adsorbing on the NPs. This is in fact what is observed on the ACFs (Figure S7-b), which present a time decay at short times whose intensity increases with increasing concentration of γ -globulin. However, no clear changes are observed in the ACFs at longer times, indicating the total absence of aggregation. These results were confirmed by the size distribution obtained from the ACF fits: the number distribution shows no contribution of the NPs even at the lowest concentrations (Figure S7-c), but exhibits a peak at 10-12 nm corresponding to the size of the γ -globulin. On the other hand, in the intensity distribution (Figure S7-c), the NP contribution was clearly visible in all cases due to the higher contribution of the larger size to the measured signal. The intensity distributions show that the NPs were stable at the different concentrations of γ -globulins (10-45 mg/mL), with a size distribution peaking at less than 200 nm, thus confirming the colloidal stability of the **NP** in the presence of γ -globulin.

Finally, the colloidal stability of the functionalized NPs was investigated in an environment composed of a combination of individually tested proteins at their highest concentrations, *ie* in SBF with 60 mg/mL of BSA and 45 mg/mL of γ -globulin. A small quantity (1 mg/mL) of glucose was also added to better simulate the plasma composition. Figure S8 presents the measured ACF together with the calculated fit. The latter was obtained by least square fitting and considering two independent exponential functions: one for the contribution of the small molecules and one for the contribution of the NPs. The derived characteristic time for the NPs is $\tau = 1140 \mu\text{s}$, which corresponds to a mean hydrodynamic diameter of 250 nm. This is in agreement with the previous observation of a slight aggregation upon addition of 60 mg/mL albumin to the solution. This result is promising as it indicates that no further aggregation appears under these drastic conditions.

The previous measurements highlight a particularly good colloidal stability, with only minor aggregation of the NPs observed upon adding BSA at 60 mg/mL. However, since standard DLS

measurements are carried out in a large observation volume of several mm³, many NPs are illuminated at the same time and the measured size distributions average the different sizes of the NPs. Therefore, possible NP size heterogeneities that appear in the early stages of the aggregation process could be missed. On the contrary, when performing DLS experiments in a small observation volume, only a few tens of NPs diffuse during the whole acquisition time of a few seconds and the presence of a unique aggregate that scatters much more light than the small NPs is sufficient to modify the entire ACF. The former can therefore be detected even at very low concentrations.

To support the results obtained from the standard DLS measurements, DLS studies under our confocal microscope were therefore undertaken on the NP solutions containing SBF and an increasing concentration of BSA, ranging from 6 to 60 mg/mL. As before, ten ACFs were measured for each BSA concentration and the mean ACFs are shown in Figure 6. The latter were normalized to ease the comparison of the characteristic times. At 6 and 15 mg/mL of BSA the ACFs present a mean characteristic time $\tau_D = 3.2$ ms and $\tau_D = 3.5$ ms, respectively, slightly higher than the mean characteristic time, $\tau_D = 3$ ms, of the NPs with no BSA, but within the range of 2.5-4 ms due to the natural size dispersion of the NPs. At 30 and 60 mg/mL of BSA, the ACFs exhibit a mean characteristic time $\tau_D = 4.2$ ms and $\tau_D = 5.5$ ms, respectively, which are higher than the value for the non-aggregated NPs and increase with increasing concentration of BSA. These first results confirm the previous observation of the absence of aggregation for 6 and 15 mg/mL of BSA, the broadening of the size distribution at 15 mg/mL corresponding to a slightly larger mean characteristic time; and the start of an aggregation process at 60 mg/mL of BSA. The ten different ACFs performed for each concentration were also analyzed individually. For each concentration, the measured ACFs were separated into two categories: those with a characteristic time within the range 2.5-4 ms for the individual NPs and those with higher characteristic time. The mean ACF of

each category is displayed in Figure S10, for the four concentrations in BSA and in Figure 6-b for the 60 mg/mL concentration. Up to 30 mg/mL, the majority of the ten measured ACFs exhibit characteristic times consistent with the diffusion of individual NPs with mean diffusion times $\tau_D = 2.8 - 3.2$ ms, corresponding to the expected hydrodynamic diameter $d_H = 150-180$ nm. For these three concentrations, only one or two ACFs out of ten exhibit a higher characteristic time corresponding to the diffusion of small aggregates typically composed of 2-5 NPs.^{52,55} At a BSA concentration of 60 mg/mL, we observe a larger number of ACFs exhibit characteristic times which are not consistent with the diffusion of individual NPs, as their value range from $\tau_D = 4.5$ to 11 ms. This indicates that more and larger aggregates are formed at this concentration as compared to the lower concentrations, thereby confirming the beginning of an aggregation process.

Finally, the concentration of the individual NPs within the four different solutions was estimated from the ACFs with no aggregates. The obtained mean and individual values are displayed in Figure 6-c for each concentration in BSA as well as for the NPs solution with no BSA. The blue rectangle indicates the width of the error bar on the estimation of the initial NP concentration. One can observe that the concentration of the individual NPs is stable at 6 to 15 mg/mL in BSA and decreases slightly at 30 mg/mL (although the measured value is still the same within the error bars), excluding the coagulation of the NPs. On the contrary, an actual decrease in the concentration of individual NPs is observed at 60 mg/mL in BSA, which again is consistent with an aggregation process. However, even in this latter case, almost half of the initial individual NPs are still present as isolated NPs in the solution.

Figure 6 : (a) Mean ACFs normalized to one measure of the NPs solutions with 0 (black line), 6 (light red), 15 (dark red), 30 (light blue) and 60 mg/mL of BSA (dark blue). (b) at 60 mg/mL of BSA, the average ACF is the sum of two of ACFs: one corresponding to the diffusion of isolated NPs with a mean characteristic time of 2.5 ms (dark blue) and one corresponding to the diffusion of small aggregates with a mean characteristic time of 7.5 ms and values ranging from 4.5 to 11 ms depending on the different ACFs. (c) Mean concentration of the isolated NPs (gray dots) and concentration extracted from the different ACFs (Blues crosses) as a function of the BSA concentration.

Figure 7 shows the resonant one-photon absorbance spectrum of the aqueous solution of the **NP-I-PEG** superimposed with their two-photon excitation spectrum, and its one- and two-photon excited fluorescence spectra. The linear absorbance spectrum exhibits a maximum at 464 nm. As shown earlier,³⁹ this large absorbance is associated with a charge transfer transition characteristic of donor-acceptor type structures. The absorbance spectrum is further broadened by light scattering due to the relatively large particles giving a non-negligible contribution even above 600 nm. The two-photon absorbance spectrum (Figure 7-a) peaks at 930 nm with a σ_2 value of 49 ± 15 GM per chromophore. This spectrum appears to be narrower than its linear counterpart, which we attribute to the stronger influence of scattering on the latter. The spectral overlap between both spectra is due to the excitation of the lowest excited state of the molecule in both cases, in agreement with its symmetry.

Figure 7 : a) Absorbance spectrum of aqueous solution of **NP-I-PEG** (black) superposed with their two-photon absorption spectrum per chromophore unit in the NP (red). b) One- (black) and two-photon (red) absorption induced fluorescence spectra of the **NP-I-PEG**.

The one and two-photon excitation induced fluorescence (TPEF) spectra exhibiting maxima at around 630 nm are in good agreement (Figure 7-b). The small discrepancy between the two spectra is probably due to the strong scattering of the exciting laser in the TPEF experiments. The overall NP brightness ($\phi_f \times \sigma_2^{\max} \times N_{NP}$), which is the main parameter to demonstrate the potential of these objects for imaging applications, was calculated from the fluorescence quantum yield, the two-photon cross section and the estimated number of fluorophores per NP.⁵⁶ This yields a very high value of $(3.0 \pm 0.9) \times 10^6$ GM per NP, due to the very large number of dye molecules present in each NP (*ca* 2×10^6 fluorophores/NP in a 170 nm NP; see supporting information).³⁶ This represents a significant advantage of these NP, since they will be imaged as a very bright spot, in contrast to the case of NPs where the dyes are diluted within a matrix.

To demonstrate the imaging potential of these nanoparticles, we first decided to study their ability to penetrate MCF-7 human breast cancer cells in culture and to emit luminescence. The biocompatibility of **NP-I-PEG** was firstly studied. The toxicity of **NP-I-PEG** on MCF-7 was investigated in the dark (for 72 h) and exposed or not to sunlight (4 h). The results demonstrated a

decrease in living cells according to the increase in **NP-I-PEG** concentration but no influence of light on cytotoxicity (Figure S11). Then, MCF-7 cells were incubated with **NP-I-PEG** ($10 \mu\text{g.mL}^{-1}$) for 24 h and imaged using a confocal microscope equipped with a Chameleon pulsed laser. The brightness of **NP-I-PEG** inside living cells under 450 nm (continuous laser) or 900 nm (pulsed laser) excitation are compared in Figure S12. Cells were stained with a green CellMask revealing cells outline in green. Inside the cells, relatively weak red spots are observed under 450 nm excitation wavelength, suggesting that NPs are internalized within the cells. In contrast, under two-photon excitation (900 nm), the **NP-I-PEG** demonstrated a much higher brightness, resulting in the red coloration of all cells. The pictures displayed in Figure S12 demonstrate the significant potential of **NP-I-PEG** as fluorophores for bio-imaging under two-photon excitation in the NIR region.

In order to determine the sub-cellular localization of **NP-I-PEG**, confocal fluorescent imaging analysis was performed on living MCF-7 incubated with $25 \mu\text{g.mL}^{-1}$ of **NP-I-PEG** in the presence of cell mask, Hoechst 33342 (nuclei staining), or LysoTracker (lysosomes staining). As shown in figure 8, at this concentration, the NP exhibit a tremendous brightness, mainly under an excitation at 900 nm using a pulsed laser. The first lane (cell membrane staining) confirms that the NPs are well inside the cells, the second one shows the perinuclear localization of the NPs, while the third one demonstrates a strong co-localization rate of NPs and lysosomes, suggesting an endo-lysosomal pathway for the internalization of **NP-I-PEG** inside the cancer cells studied here.

Figure 8 : Subcellular localization of **NP-I-PEG** in living breast cancer cells (MCF-7). MCF 7 cells were incubated for 24 h with $25 \mu\text{g.mL}^{-1}$ of **NP-I-PEG**. Cells were washed twice and imaged using confocal microscope Zeiss LSM 780 laser beam at 450 nm or at 900 nm (pulsed laser, Chameleon), magnification $\times 63$. Cell membranes were stained with cell mask (green); nuclei were stained by Hoechst 33342 (blue); lysosomes were stained with LysoTracker green and compounds were visualized in red. Scale bar: $10 \mu\text{m}$.

The potential for in vivo, two-photon fluorescence imaging was then probed on CX3CR1-GFP mice, expressing GFP only in microglia in the brain. Imaging was performed through the thinned skull using a two-photon microscope with a Ti:Sapphire laser operating at an excitation wavelength of 920 nm. The optical background noise in the blood vessels of a CX3CR1-GFP mouse was first recorded prior to injection of NPs. Following this, $200 \mu\text{L}$ of a **NP-I-PEG** suspension in PBS ($80 \mu\text{g/mL}$ NPs corresponding to $32 \mu\text{g/mL}$ dye), were introduced into the mouse through retro-orbital injection. Imaging was performed within 30 seconds post injection, which enabled the visualization of the NPs in the blood vessels (ϕ *ca* 20 and $40 \mu\text{m}$), where they appeared as bright red spots in the red channel (Figure 9). Since the fluorescence intensity of the surrounding glial cells in the green channel did not evolve much with time, this was used as a reference to ascertain the fluorescence intensity of the circulating NPs at different time points. These red spots

corresponding to NP varied in size and intensity, with some brighter than the others, which was attributed either to the presence of the NPs in the focal plane of the microscope or to the presence of a small percentage of aggregates of NPs, whose presence was demonstrated in the DLS studies in small observation volumes. Moreover, these bright NPs were observed to flow through the blood stream, without adhering to the walls of the blood vessels, an indication of their colloidal stability.

Figure 9 : Circulation of NPs in blood vessels; (a) green channel (GFP microglia in the brain) and red channel (blood vessel due to presence of NP; b) red channel only. Image size 200×200 μm^2

A significant drop in fluorescence intensity (Figure 11-a) was recorded within 15-20 minutes of imaging, indicating the possible clearance of the biggest NPs and aggregates from the bloodstream (Figure 11-b). Although the functionalized NPs are colloiddally stable in biological media, it has been reported that NPs larger than a few tens of nm are easily detected and cleared by the macrophages, while smaller NPs can circulate for longer periods of times.⁵⁷ This further explains the scarce bright spots and faint fluorescence that is seen in the blood vessels even after a long time post injection, which could be due to the smaller sized NPs that are still circulating in the blood stream. It is obvious from Figure S13 that the fluorescence drops to a much lower signal within 5 minutes, but that some NPs still circulate the blood stream although fewer in number due to the elimination of the largest NPs.

However, even with this drop in fluorescence intensity, these bright spots were still visible even after 15 minutes post injection, indicating the circulation of the NPs in the bloodstream. This was

further confirmed in Figure S13-b, where fluorescing NPs were still clearly visible after 15 minutes post injection.

Conclusion

We demonstrated here the potential of ultrabright silica-coated organic nanocrystals for bio-imaging. These NPs containing crystalline emitters, specifically engineered to exhibit two-photon absorption and emission properties for two-photon bio-imaging. The NPs were functionalized with PEG chains (Mn: 5000), using CuAAC click chemistry to render them “stealthy” within the blood stream and improve their colloidal stability. The colloidal stability of the NPs was tested in different media with increasing levels of complexity starting with simulated body fluid (SBF) and different plasma proteins in increasing concentrations. The ACFs of NPs in SBF and varying concentrations of γ -globulins (10-45 mg/mL) demonstrated their colloidal stability, with no significant increase in mean size distribution being observed. A slight shift of the ACFs was observed towards longer decay times for high BSA concentrations (30 and 60 mg/mL), indicating an increase in the solution polydispersity under these conditions. Finally, the colloidal stability of the functionalized NPs was investigated in an environment composed of a combination of individually tested components at their highest concentrations, *ie* in SBF with 60 mg/mL of BSA, 45 mg/mL of γ -globulin together with 1 mg/mL of glucose. Under such drastic conditions, no further aggregation was evident. These standard DLS results were further corroborated with small-volume DLS studies, which enabled the observation of a much smaller number of NPs thereby reducing the averaging aspect of standard DLS experiments. Spectroscopic characterization of the colloidal NP suspensions indicated a fluorescence quantum yield of 3% and also showed good agreement between the one and two-photon excitation induced fluorescence spectra peaking at ~630 nm, with a maximal σ_2 value of

50±15 GM per molecule at 930 nm. This results in a very high brightness per NP of (3.0±0.9) × 10⁶ GM. The potential of these NPs for imaging was validated *in vitro* in MCF-7 human breast cancer cells, *and in vivo* in CX3CR1-GFP mice, using two-photon imaging, where they appeared as bright red spots in the blood vessels. The NPs remained in circulation for several minutes post injection and without any adherence to the walls of the blood vessels, showing their potential for bio-imaging. Although a drop in fluorescence intensity was recorded after 15-20 minutes of imaging, corresponding to the clearance of the larger NPs by the reticulo-endothelial system, the smaller NPs remained in circulation and were detectable. These promising results show the potential of these unique nanotracers for bio-imaging applications. Studies are underway to further reduce the size distribution of the NPs to achieve longer circulation times.

Acknowledgements
