## GRAPHICAL ABSTRACT

- $\text{TiO}_x$  REM was used for the first time as anode in EF process.
- $\cdot\text{OH}$  were generated in retentate and at REM with optimal mass transport conditions.
- The efficiency of REM/EF integrated process far exceeded that of standalone processes.
- High mineralization current efficiency (77%) was obtained with REM/EF process.
- Synergy was observed from degradation in the bulk and mineralization at the  $\text{TiO}_x$  REM.

Water treatment

Sub-stoichiometric titanium oxide ( $\text{TiO}_x$ ) reactive electrochemical membrane (REM) were integrated for the first time as anode in the electro-Fenton (EF) process. Hydroxyl radicals ( $\cdot\text{OH}$ ) were produced both in the retentate from Fenton's reaction and at the REM from anodic oxidation (AO). Optimal mass transport conditions were implemented because of convection-enhanced mass transport of (i) organic pollutants towards the REM surface during filtration and (ii) dissolved  $\text{O}_2$  towards cathode active sites owing to the use of a 3D carbon felt cathode in flow-through configuration for  $\text{H}_2\text{O}_2$  generation. The efficiency of the REM/EF process was much higher than EF or REM used as standalone processes. For instance, taking paracetamol as target pollutant,  $(67 \pm 2)\%$  removal of  $55 \text{ mg L}^{-1}$  of initial TOC was achieved with a high mineralization current efficiency (MCE) of  $(43 \pm 1)\%$ . By comparison, standalone REM and EF processes achieved only 47% (MCE = 30%) and 31% (MCE = 20%) of TOC removal, respectively. By monitoring TOC removal both in retentate and permeate, the effect of homogeneous oxidation in the bulk retentate and heterogeneous oxidation at the REM could be observed separately. It was thus highlighted that the efficiency of AO might be affected by the presence of  $\cdot\text{OH}$  and  $\text{Fe}^{2+}$  in the bulk. It was also emphasized a synergistic effect related to the formation of carboxylic acids in the bulk retentate that are more easily mineralized at the REM where both  $\cdot\text{OH}$ -mediated oxidation and direct electron transfer occur.

## 1. Introduction

Water treatment is currently a key focus for environmental engineering. In most of countries, water supply and recycling (e.g. in industrial processes) as well as protection of natural water resources are currently crucial issues. Particularly, the removal of biorefractory organic pollutants is one of the main challenges [1]. In this context, the development of electrochemical advanced oxidation processes (EAOPs) is currently a major topic of interest [2–5]. They have several technical advantages, including low (or zero) consumption of chemical reagents, process automation and compact reactor design [6,7].

EAOPs are based on the generation of hydroxyl radicals ( $\cdot\text{OH}$ ) which are able to degrade and/or completely mineralize of a wide range of biorefractory organic compounds with fast kinetics [8–17]. Firstly,  $\cdot\text{OH}$  can be produced homogeneously in the solution by the electro-Fenton process based on Fenton's reaction (Eq. (1)) [18–20]. Hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) is generated by the two-electron reduction of dissolved  $\text{O}_2$  at carbon-based cathodes (Eq. (2)), while a catalytic amount of ferrous iron is sufficient to start the Fenton's reaction (Eq. (3)). Then,  $\text{Fe}^{2+}$  ion (catalyst) is generated/regenerated at the cathode from reduction of  $\text{Fe}^{3+}$  formed in Eq. to ensure continuous generation of  $\cdot\text{OH}$  (Eq. (3)) [21]. Secondly,  $\cdot\text{OH}$  can be also generated heterogeneously (AO) through water oxidation at the surface of anodes with high overpotential for oxygen evolution reaction (Eq. (4)) [7,22–25].

The electron is the main reagent during EAOPs, thus the Faraday efficiency is a crucial parameter for assessing process efficiency [7]. Parasitic and wasting reactions must be minimized so that the electrons supplied to the system are used effectively for the degradation and mineralization of pollutants. Because of the short lifetime of  $\cdot\text{OH}$ , low Faraday efficiency usually results from mass transport limitations [2,26,27]. For example, anodic oxidation (AO) is a heterogeneous electro-catalytic process during which physisorbed  $\cdot\text{OH}$  are generated at the anode surface, thus resulting in a thin reactive layer close to the anode surface (less than  $1\ \mu\text{m}$ ). Therefore, process efficiency is often limited by the diffusion boundary layer at the solution/electrode interface ( $\approx 100\ \mu\text{m}$ ) [27]. Recently, the use of sub-stoichiometric titanium oxide ( $\text{TiO}_x$ ) reactive electrochemical membrane (REM) as anode has been developed [27–33]. Such anode material is able to strongly enhance current efficiency because of the higher electro-active surface area and convection-enhanced mass transport of pollutants from the bulk to the anode in flow-through operation [27,29,33,34]. Such material also represents a promising alternative to boron-doped diamond electrodes for reducing capital expenditures of electrochemical systems [35]. Besides,  $\text{H}_2\text{O}_2$  production for the EF process can be also limited by mass transport issues because of the low solubility of  $\text{O}_2$  in water. Thus, recent studies have developed 3D flow-through carbon-based cathode for production of large amounts of  $\text{H}_2\text{O}_2$  [36–39]. The objective is to improve mass transport of dissolved  $\text{O}_2$  to cathode active sites.

In the present study, it is proposed for the first time, the integration of  $\text{TiO}_x$  REM as anode in the EF process. 3D flow-through carbon felt (CF) was used as cathode. The objective is to achieve mineralization of organic compounds with high current efficiency owing to optimal mass transport conditions. Optimal conditions for  $\text{H}_2\text{O}_2$  production were identified and the efficiency of various configurations (REM alone, EF alone, REM/ $\text{H}_2\text{O}_2$  and REM/EF) for the removal of a model pharmaceutical residue (paracetamol) were compared in order to emphasize the suitability of the new REM/EF process. Moreover, by using  $\text{TiO}_x$  REM as anode and without recirculation of the permeate, it was possible to well differentiate the oxidation of organic compounds by either

homogeneous reactions in the bulk (TOC removal in the retentate) or heterogeneous reactions at the  $\text{TiO}_x$  REM (TOC removal between retentate and permeate). Thus, this study allowed the identification for the first time of antagonist and synergistic phenomena occurring when EF and AO processes are integrated into a single reactor.

## 2. Materials and methods

### 2.1. Chemicals

All chemicals were of reagent grade and purchased from Sigma Aldrich. Aqueous solutions were prepared with deionized water ( $R > 18\ \text{M}\Omega\ \text{cm}$ ).

### 2.2. Electrode materials

Anode materials were  $\text{TiO}_x$  REM supplied by Saint-Gobain Research Provence (CREE Cavillon, France). This porous material was synthesized from carbothermal reduction of  $\text{TiO}_2$  by using an extrusion die, based on the method developed by Saint-Gobain Research Provence. The synthesis method starts from a mixture of anatase  $\text{TiO}_2$ , carbon black, organic binders and water. Then a debinding step followed by a sintering and carbothermal reduction step performed during 2 h at  $1300\ ^\circ\text{C}$  under argon atmosphere allows for the formation of this porous material. Additional details on the synthesis method are provided in Trellu et al. (2018) [28]. These anodes are a mixture of  $\text{Ti}_4\text{O}_7$  and  $\text{Ti}_5\text{O}_9$  Magnéli phases. They have a monodispersed pore size distribution, with a median pore size of  $1.4\ \mu\text{m}$ , a porosity (pore volume) of 41% and a specific surface area of  $0.40\ \text{m}^2\ \text{g}^{-1}$ . The water permeability of these  $\text{TiO}_x$  membranes is  $3300\ \text{L}\ \text{m}^{-2}\ \text{h}^{-1}\ \text{bar}^{-1}$ . The characteristics of materials obtained were detailed Trellu et al. (2018) [28] (scanning electron microscopy images, HF intrusion porosimetry and X-ray diffraction data are provided as [Supplementary Material](#)). Electrodes were stable in the range of current density and exploitation duration required for this study. Long-term stability tests are the focus of on-going studies. Cathode materials were 6.35 mm thick CF supplied by Alfa Aesar.

### 2.3. Experimental installation

The schematic diagram of the experimental installation is shown in Fig. 1.

$\text{TiO}_x$  REM (inside/outside diameter = 6/10 mm, active outer surface  $27.6\ \text{cm}^2$ ) was used as anode with the solution flowing from the outside (retentate) to the inside (permeate) of the tube. CF cathode ( $15 \times 8\ \text{cm}^2$ , 6.3 mm thick) was placed concentrically around the REM with an inter-electrode distance of 3.5 cm.  $\text{O}_2$  was injected in the tank

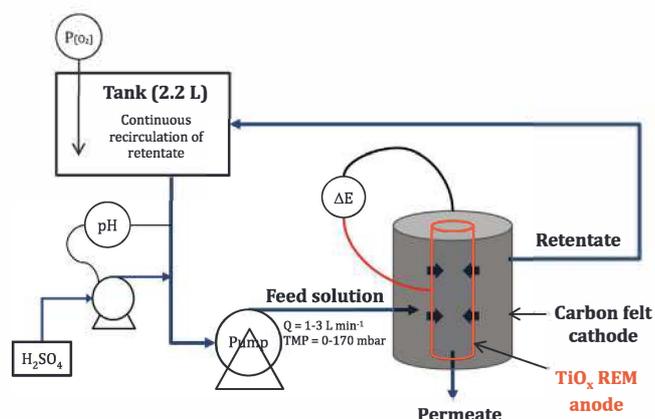

Fig. 1. Scheme of the experimental installation (without recirculation of the permeate) equipped with a tubular anodic  $\text{TiO}_x$  REM and a cathodic carbon felt placed concentrically around the REM in the retentate compartment.

by bubbling fine bubbles of O<sub>2</sub> in the solution. Experiments were carried out with paracetamol (PCT) as a model organic pollutant with initial total organic carbon content (TOC<sub>0</sub>) of 55 or 110 mg L<sup>-1</sup>. Sodium sulfate at low concentration (5 mM) was used as supporting electrolyte. The total volume of the treated solution was 2.2 L for all experiments (meaning that the ratio between the geometric surface area of the anode and the volume of solution was 0.0125 cm<sup>-1</sup>). For the EF process, 0.2 mM of Fe<sup>2+</sup> was initially added to the solution to be treated. The pH was initially adjusted to 3.0 with H<sub>2</sub>SO<sub>4</sub>, in accordance with the optimal pH for the EF process [6]. An injection system of H<sub>2</sub>SO<sub>4</sub> in the retentate, controlled by a pH regulation, maintained the pH value between 2.9 and 3.1 in the retentate during operation of EF without recirculation of the permeate.

The process was operated without continuous feed of the reactor and the retentate was continuously recirculated at 100% for all experiments. When entering the electrochemical cell, the solution is first forced to flow through the CF cathode. Then, a portion of the solution flows through the REM according to the transmembrane pressure (TMP) and is collected as permeate. The rest of the solution is forced to flow again through the CF before to come back to the feed tank. A recirculation pump was used to adjust the retentate recirculation flow rate in the range of Q = 1–3 L min<sup>-1</sup>. TMP was in the range 0–170 mbar. The experiments were carried out either by continuously collecting the permeate or by recirculating the permeate at 100% in the feed tank (retentate). All experiments were carried out in galvanostatic mode, using an ELC power supply (AL924A). The current density (j) was adjusted between 6 and 30 mA cm<sup>-2</sup> (always calculated from the geometric surface of the anode). The experiments were conducted systematically for 5 h.

Different processes have been tested depending on operating conditions, which are given in Table 1:

#### 2.4. Analytical procedures

PCT concentration was measured by HPLC (Agilent 1200 system) with C18 column and UV detector (λ = 254 nm). The mobile phase was a mixture of water and acetonitrile containing 0.1% v/v formic acid. HPLC was operated at a constant flow rate of 1.0 mL min<sup>-1</sup> using a gradient elution as described previously [40].

TOC was measured with a Shimadzu TOC-L analyzer using the catalytic oxidation combustion method at 680 °C. The relative standard deviation on TOC measurements was 2%. Percentage of TOC removal in the retentate at time t was calculated using Eq. (5). Percentage of TOC removal in the permeate at time t was calculated using Eq. (6). Global percentage of TOC removal (taking into consideration TOC removal in both retentate and permeate) at the end of the experiment was calculated using Eq. (7).

$$\text{TOC removal in the retentate (t) (\%)} = \left(1 - \frac{\text{TOC}_{\text{ret,t}}}{\text{TOC}_0}\right) \times 100 \quad (5)$$

**Table 1**

Operating conditions used for the different processes. The feed/retentate recirculation flow rate was controlled at Q = 1 L min<sup>-1</sup> for all configurations. TMP: transmembrane pressure; EF: electro-Fenton; REM: reative electrochemical membrane.

Process	TMP (mbar)	O <sub>2</sub> supply	[Fe <sup>2+</sup> ] (mM)
EF	0	yes	0.2
Electro-Fenton in the bulk retentate with low anodic oxidation at the REM	(no permeate flux)		
REM	30	no	0
Anodic oxidation at the REM			
REM/H <sub>2</sub> O <sub>2</sub>	30	yes	0
AO at the REM and generation of H <sub>2</sub> O <sub>2</sub> in the bulk retentate			
REM/EF	30	yes	0.2
Electro-Fenton in the bulk retentate and AO at the REM			

$$\text{TOC removal in the permeate (t) (\%)} = \left(1 - \frac{\text{TOC}_{\text{per,t}}}{\text{TOC}_{\text{ret,t}}}\right) \times 100 \quad (6)$$

$$\begin{aligned} \text{Global TOC removal (\%)} \\ = \left(1 - \frac{(\text{TOC}_0 - \text{TOC}_{\text{per}}) \times V_{\text{per}} + (\text{TOC}_0 - \text{TOC}_{\text{ret}}) \times V_{\text{ret}}}{\text{TOC}_0 \times V_0}\right) \times 100 \end{aligned} \quad (7)$$

where TOC<sub>ret,t</sub> and TOC<sub>per,t</sub> are TOC concentrations in the retentate and permeate at time t, and 0 (initial concentration); TOC<sub>ret</sub> and TOC<sub>per</sub> are TOC concentrations in the retentate and permeate at the end of the experiment; TOC<sub>0</sub> is the initial concentration of TOC; V<sub>ret</sub> and V<sub>per</sub> are the volumes of retentate and permeate at the end of the experiment; V<sub>0</sub> is the initial volume of the feed solution.

Mineralization current efficiency (MCE) was calculated using the following equation (Eq. (8)) for assessing the Faraday efficiency of the process for mineralization of PCT.

$$\text{MCE(\%)} = \frac{\Delta\text{TOC}_{\text{exp}}}{\Delta\text{TOC}_{\text{th}}} \times 100 \quad (8)$$

where ΔTOC<sub>exp</sub> is the amount of TOC removed during experiments and ΔTOC<sub>th</sub> is the theoretical TOC removal calculated by assuming that the electrical charge was only consumed for mineralization of PCT.

H<sub>2</sub>O<sub>2</sub> electrochemically generated in the retentate was analyzed by a spectrophotometric method, based on the measurement of the absorbance at 410 nm of a colored complex (titanium peroxy sulfate) formed in the presence of Ti<sup>4+</sup> in sulfuric acid medium [41]. Current efficiency for H<sub>2</sub>O<sub>2</sub> production was calculated similarly to MCE, based on the amount of H<sub>2</sub>O<sub>2</sub> measured during experiments and the theoretical amount of H<sub>2</sub>O<sub>2</sub> that could be produced by assuming that the electrical charge was only consumed for the two electron reduction of O<sub>2</sub> (Eq. (2)). Accumulation rate of H<sub>2</sub>O<sub>2</sub> was calculated using Eq. (9).

$$\begin{aligned} \text{H}_2\text{O}_2 \text{ accumulation rate (t}_i\text{) (mg min}^{-1}\text{)} \\ = \frac{[\text{H}_2\text{O}_2]_{t_i} \cdot V_{\text{ret},t_i} - [\text{H}_2\text{O}_2]_{t_{i-1}} \cdot V_{\text{ret},t_{i-1}}}{t_2 - t_1} \end{aligned} \quad (9)$$

where [H<sub>2</sub>O<sub>2</sub>]<sub>t<sub>i</sub></sub> and [H<sub>2</sub>O<sub>2</sub>]<sub>t<sub>i-1</sub></sub> are concentrations in mg L<sup>-1</sup> at time t<sub>i</sub> and t<sub>i-1</sub> (min), respectively. Similarly, V<sub>ret,t<sub>i</sub></sub> and V<sub>ret,t<sub>i-1</sub></sub> are the volumes of retentate (L) at time t<sub>i</sub> and t<sub>i-1</sub>, respectively.

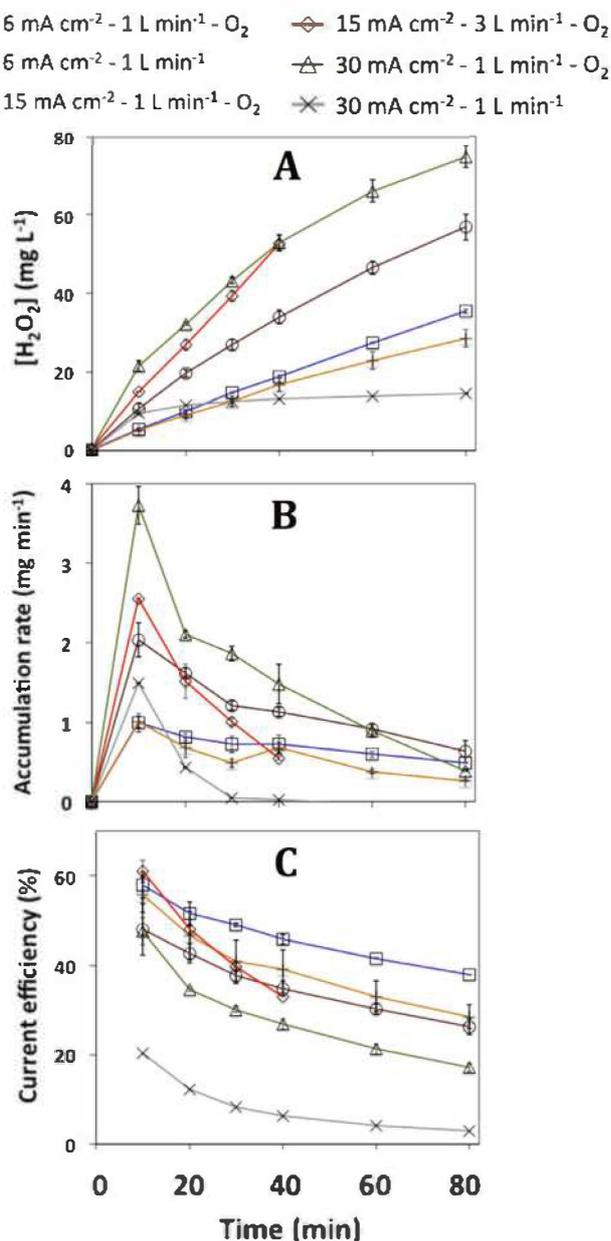

Oxamic acid was identified and quantified by ion-exclusion HPLC equipped with a BENSON column (300 mm, 7.8 mm (i.d.)) and using a refractive index detector (Waters 2414). Column temperature was set at 30 °C. A solution of 1.5 mM H<sub>2</sub>SO<sub>4</sub> was used as mobile phase with isocratic elution at 0.4 mL min<sup>-1</sup>.

Some experiments were carried out in triplicate in order to assess the reproducibility of experimental data.

### 3. Results and discussion

#### 3.1. H<sub>2</sub>O<sub>2</sub> production

The first set of experiments aimed at evaluating the capacity of the

**Fig. 2.** Evolution over time of: (A) concentration of H<sub>2</sub>O<sub>2</sub> in the retentate, (B) accumulation rate (mg min<sup>-1</sup>) of H<sub>2</sub>O<sub>2</sub> in the retentate, as a function of current density ( $j = 6, 15$  or  $30 \text{ mA cm}^{-2}$ , corresponding to  $1.4, 3.5$  or  $6.9 \text{ mA cm}^{-2}$  for the carbon felt cathode), recirculation flow rate of the retentate ( $Q = 1$  or  $3 \text{ L min}^{-1}$ ) and O<sub>2</sub> supply (with or without). All experiments have been performed in deionized water with  $5 \text{ mM}$  of Na<sub>2</sub>SO<sub>4</sub>. Data above 40 min have not been measured for the experiment at  $3 \text{ L min}^{-1}$  because of the higher TMP that decreased rapidly the volume of the retentate. Error bars have been calculated from replicate experiments ( $n = 3$ ).

system to produce H<sub>2</sub>O<sub>2</sub> for the EF process, according to current density, recirculation flow rate and O<sub>2</sub> supply. Results are presented in Fig. 2. Generation of H<sub>2</sub>O<sub>2</sub> is based on dissolved O<sub>2</sub> reduction at the cathode. At low current density ( $6 \text{ mA cm}^{-2}$ ), the consumption of dissolved O<sub>2</sub> was low (Fig. 2A). Therefore, O<sub>2</sub> supply only slightly increased H<sub>2</sub>O<sub>2</sub> production rate because O<sub>2</sub> transfer from the gas phase to the liquid phase into the tank was almost sufficient to counterbalance O<sub>2</sub> reduction at the cathode. However, at high current density ( $30 \text{ mA cm}^{-2}$ ), O<sub>2</sub> reduction rate at the cathode was strongly increased. Without O<sub>2</sub> supply, H<sub>2</sub>O<sub>2</sub> accumulation rate rapidly decreased to 0. In

fact, the concentration remained constant after 30 min of operation while the volume of retentate was continuously decreasing; therefore the amount of H<sub>2</sub>O<sub>2</sub> in the reactor was actually lower at 80 min than at 30 min. These results highlight that O<sub>2</sub> supply is mandatory for maintaining the H<sub>2</sub>O<sub>2</sub> production rate.

For all experiments with O<sub>2</sub> supply, the accumulation rate of H<sub>2</sub>O<sub>2</sub> decreased with time. experiment. (Fig. 2B). Generation of H<sub>2</sub>O<sub>2</sub> was assumed to be constant during experiments since O<sub>2</sub> was supplied in excess. However, the accumulation of H<sub>2</sub>O<sub>2</sub> comes from the difference between generation and destruction of H<sub>2</sub>O<sub>2</sub>. In this configuration, destruction of H<sub>2</sub>O<sub>2</sub> can be ascribed to both cathodic reduction (Eq. (10)) and anodic oxidation (Eq. (11)). These reactions are promoted at high H<sub>2</sub>O<sub>2</sub> concentration, explaining thus the decrease of H<sub>2</sub>O<sub>2</sub> accumulation rate during all experiments as well as the stronger relative decrease of H<sub>2</sub>O<sub>2</sub> accumulation rate with time when operating the process at high current density (for which higher concentration of H<sub>2</sub>O<sub>2</sub> was reached).

After operating the process during 30 min at  $30 \text{ mA cm}^{-2}$  (corresponding to  $6.9 \text{ mA cm}^{-2}$  for the CF cathode),  $(79 \pm 2) \text{ mg}$  of H<sub>2</sub>O<sub>2</sub> was accumulated in the retentate ( $2.2 \text{ L}$ ). In a recent study of Pérez et al. (2016) reported the accumulation of around  $260 \text{ mg}$  of H<sub>2</sub>O<sub>2</sub> (in  $1 \text{ L}$ ) after 30 min using polytetrafluoroethylene-modified carbon felt at  $50 \text{ mA cm}^{-2}$  [36]. The Venturi-based jet cell used in this study was reported to be as efficient as conventional gas diffusion electrode. By comparing these results, one can conclude that the system developed in the present study seems to be highly competitive, since the amount of H<sub>2</sub>O<sub>2</sub> accumulated was only 3.3 times lower by using a current density 7.2 times lower with a non-modified carbon felt cathode.

High current efficiency for H<sub>2</sub>O<sub>2</sub> production (between 30 and 50% after 30 min) was observed whatever the current density applied for experiments performed with O<sub>2</sub> supply (Fig. 2C). The high efficiency of the reactor was ascribed to operation of the process under flow-through mode with continuous recirculation of the retentate through the CF cathode, thus allowing a convection-enhanced mass transport of dissolved O<sub>2</sub> to cathode active sites [36].

The influence of this convection-enhanced mass transport was further investigated by increasing the recirculation flow rate from  $1$  to  $3 \text{ L min}^{-1}$  for experiments performed at  $15 \text{ mA cm}^{-2}$  and with O<sub>2</sub> supply (Fig. 2). Higher recirculation flow rate increased the TMP ( $30 \text{ mbar}$  at  $1 \text{ L min}^{-1}$  and  $170 \text{ mbar}$  at  $3 \text{ L min}^{-1}$ ), and subsequently, the permeate flux through the REM ( $95 \text{ L h}^{-1} \text{ m}^{-2}$  at  $1 \text{ L min}^{-1}$  and  $510 \text{ L h}^{-1} \text{ m}^{-2}$  at  $3 \text{ L min}^{-1}$ ). Within the first minutes, higher current efficiency was observed ( $(61 \pm 1)\%$ ) at  $3 \text{ L min}^{-1}$  compared to  $1 \text{ L min}^{-1}$  ( $(48 \pm 4)\%$ ) owing to the promotion of the convection-enhanced mass transport of dissolved O<sub>2</sub> towards cathode active sites. However, no significant difference of current efficiency was then observed after 40 min. In fact, higher recirculation flow rate and higher permeate flux through the TiOx REM used as anode also favored H<sub>2</sub>O<sub>2</sub> destruction following Eqs. (10) and (11), respectively. Moreover, the higher concentration reached at the beginning of the experiment also promoted H<sub>2</sub>O<sub>2</sub> destruction following Eq. (10) and Eq. (11).

As regards to the influence of current density, higher accumulation rate of H<sub>2</sub>O<sub>2</sub> was obtained at the beginning of experiments performed at high current density. However, the accumulation rate then strongly decreased with time and the current efficiency was also lower compared to experiments performed at lower current density because of the promotion of parasitic reactions involving either H<sub>2</sub>O<sub>2</sub> destruction (Eqs. (10) and (11)) or hydrogen evolution reaction (Eq. (12)).

Overall, sustainable operating conditions for H<sub>2</sub>O<sub>2</sub> production in the retentate during the REM/EF process were identified as

$j = 15 \text{ mA cm}^{-2}$  (intermediate current density), continuous  $\text{O}_2$  supply and  $Q = 1 \text{ L min}^{-1}$ . The choice of the recirculation flow rate was also selected as regards to its influence on the TMP. In fact, successful operation of the REM/EF process is based on the selection of the best compromise in terms of optimizing operating conditions for both electrochemical formation of the Fenton's reagent in the retentate and AO at the  $\text{TiO}_x$  REM. As regards to the efficiency of AO, it tightly depends on permeate and TOC flux through the  $\text{TiO}_x$  REM. Previous study on  $\text{TiO}_x$  REM revealed that optimal MCE for mineralization of PCT at  $15 \text{ mA cm}^{-2}$  was obtained for TOC flux through the REM in the range  $5\text{--}15 \text{ g m}^{-2}\text{h}^{-1}$  [28]. By using a recirculation flow rate of  $1 \text{ L min}^{-1}$  involving a TMP of 40 mbar, TOC flux through the REM could be adjusted to 5.2 and  $10.4 \text{ g m}^{-2}\text{h}^{-1}$  when performing experiments with  $\text{TOC}_0 = 55$  and  $110 \text{ mg L}^{-1}$ .

### 3.2. Process efficiency

The objective of the following experiments was to evaluate the relevance and effectiveness of the innovative integrated process, by comparing the TOC removal (mineralization) achieved with the different configurations, i.e., EF standalone process, REM standalone process, REM/ $\text{H}_2\text{O}_2$  process and REM/EF integrated process (Fig. 3). Experiments were carried out considering the optimal conditions justified in section 3.1. Experiments were performed either without recirculation of the permeate or with 100% recirculation of the permeate (meaning in this case that the volume of the retentate was constant throughout the experiment, similarly to a batch experiment) and at two different TOC concentrations ( $\text{TOC}_0 = 55$  or  $110 \text{ mg L}^{-1}$ ).

All values of percentage of TOC removal have been calculated by taking into consideration TOC removal in both retentate and permeate (Eq. (7)). For example, for the REM configuration with  $\text{TOC}_0 = 55 \text{ mg L}^{-1}$ , the percentage of TOC removal calculated from the difference between TOC in retentate and permeate was  $(90 \pm 2)\%$  (Eq. (6)). However, after 5 h of treatment, the total volume of permeate (filtrated water that passed through the REM) was 1 L. Thus, mineralization in the permeate resulted in a global percentage of TOC removal of only 41% by taking into consideration the total volume of the effluent ( $V_0 = 2.2 \text{ L}$ ).

Overall, the global percentage of TOC removal (ascribed to mineralization in both retentate and permeate, as described in Eq. (7)) with the REM configuration was only slightly higher (47%) because low

mineralization was simultaneously achieved in the retentate (non-filtrated water). In fact, very low amount of oxidizing species was generated in the bulk because of the absence of  $\text{O}_2$  supply for  $\text{H}_2\text{O}_2$  production and absence of  $\text{Fe}^{2+}$  for production of  $\cdot\text{OH}$  according to Eq. (3). By comparison, slightly higher global percentage of TOC removal was obtained with the REM- $\text{H}_2\text{O}_2$  configuration because  $\text{O}_2$  supply enhanced  $\text{H}_2\text{O}_2$  production in the retentate, which participated to oxidation of organics (TOC removal in the retentate was increased from 3 to 10% after 5 h). The best way to further promote the oxidation of organic pollutants in the retentate was to implement EF by supplying both  $\text{O}_2$  and  $0.2 \text{ mM}$  of  $\text{Fe}^{2+}$  in order to generate large amounts of  $\cdot\text{OH}$  in the retentate. Thus, EF alone achieved 31% removal of TOC after 5 h of treatment. Interestingly, the highest effectiveness was achieved with the integrated process REM/EF: the global percentage of TOC removal reached  $(67 \pm 2)\%$ . This value was 1.4 and 2.2 times higher than that obtained with REM alone and EF alone, respectively.

The efficiency of the integrated process was further highlighted by the high MCE obtained. The MCE achieved during the treatment of the solution at  $\text{TOC}_0 = 55 \text{ mg L}^{-1}$  was  $(43 \pm 1)\%$ . MCE was even further increased to 77% for the treatment of the solution at  $\text{TOC}_0 = 110 \text{ mg L}^{-1}$ . In fact, wasting reactions at high current intensity (reaction of  $\cdot\text{OH}$  with non-organic compounds, its dimerization to  $\text{H}_2\text{O}_2$  (Eq. (13)) or reaction with  $\text{Fe}^{2+}$  (Eq. (14)) are further hindered at high concentration of organic matter. These values of MCE are higher than in previously published studies on EF process in batch reactor using plate boron-doped diamond or  $\text{TiO}_x$  anode [25,42–45]. For example, Ganiyu et al. (2019) reported a lower efficiency during electro-oxidation of PCT by EF using  $\text{Ti}_4\text{O}_7$  anode. The MCE was 6% for 70% removal of  $30.2 \text{ mg L}^{-1}$  of PCT by using plate electrode in batch reactor with a current density of  $5 \text{ mA cm}^{-2}$  and a ratio between the geometric surface area of the anode and the volume of solution of  $0.10 \text{ cm}^{-1}$  [45]. In fact, electrochemical advanced oxidation processes using plate electrodes (EAOPs) are usually operated under mass transport limitation [7,26]. By comparison, the great advantage of this REM/EF process is the enhancement of the mass transport of (i) organic pollutants from the bulk to the anode surface by convection during filtration through the REM with low pore size [27,28,30] and (ii) dissolved  $\text{O}_2$  from the bulk to CF cathode active sites (for  $\text{H}_2\text{O}_2$  generation) owing to flow-through operation with continuous recirculation of the retentate through the CF cathode [36].

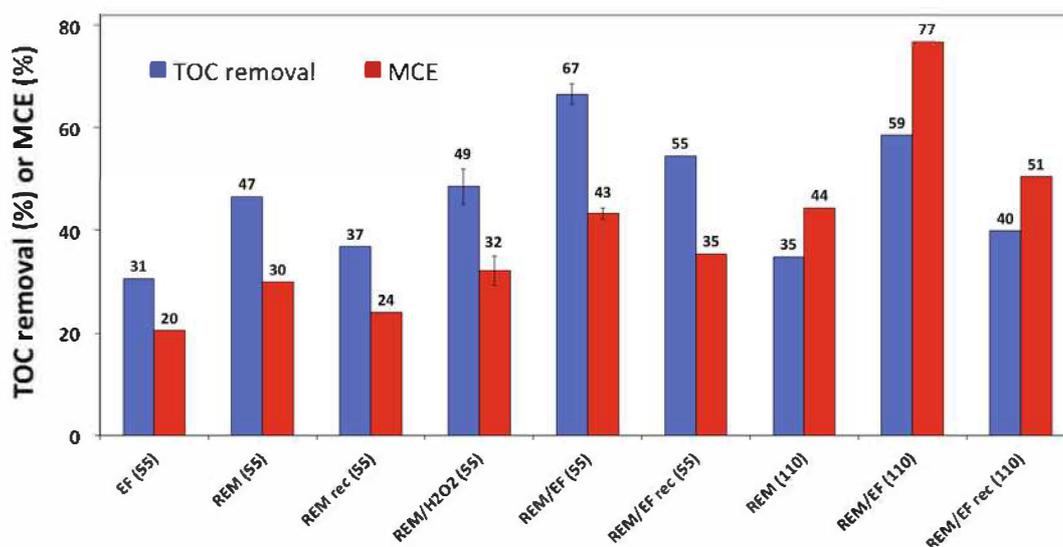

Fig. 3. Global percentage of TOC removal and MCE (%) as a function of experimental configuration (EF standalone process, REM standalone process, REM/ $\text{H}_2\text{O}_2$  process, or integrated REM/EF process) and initial TOC concentration of the paracetamol solution ( $\text{TOC}_0 = 55$  or  $110 \text{ mg L}^{-1}$ ). REM/EF rec are the experiments performed with 100% recirculation of the permeate. Error bars for REM/ $\text{H}_2\text{O}_2$  and REM/EF have been calculated from replicate experiments ( $n = 3$ ). Calculations have been made using Eqs. (7) and (8).

Experiments were also carried out by continuously recirculating the permeate into the retentate during REM/EF experiments. Therefore, similarly to a batch experiment, the total volume in the retentate remained constant throughout the experiment. TOC removal was 1.2 and 1.5 times lower compared experiments performed without recirculation at  $\text{TOC}_0 = 55$  and  $110 \text{ mg L}^{-1}$ , respectively. This lower effectiveness was due to a faster decrease of the TOC in the retentate (because of the recirculation of the permeate with low TOC content), which further promoted wasting reactions (Eqs. (10) and (11)). However, the advantage of this configuration was related to pH control. Water reduction at the cathode generates  $\text{HO}^-$  and caused a significant pH increase in the retentate ( $\text{pH} = 11.8$  after 5 h) when the process was performed without recirculation of the permeate. In this configuration, a pH regulation using  $\text{H}_2\text{SO}_4$  was therefore required for implementing the EF process in the retentate at pH between 2.9 and 3.1. Besides, water oxidation at the anode generates  $\text{H}^+$  that resulted in a strong decrease of the pH in the permeate ( $\text{pH} = 2.1$ ). Overall, it was observed that operating the process with continuous recirculation of the permeate keeps the pH in the retentate between 2.9 and 3.1 throughout the experiment, without adding  $\text{H}_2\text{SO}_4$ . Indeed,  $\text{H}^+$  generated at the anode neutralized the effect of  $\text{HO}^-$  generated at the cathode. Besides, as regards to the continuous operation of such reactor, pH regulation would depend on the way to implement the process (continuous feed of polluted water, partial recirculation of the permeate, etc.)

### 3.3. Electro-oxidation mechanisms

During the EF process, oxidant species can be generated either homogeneously in the retentate (Eqs. (1)–(3)) or heterogeneously at the anode if a suitable electrode material is used (Eq. (4)). Different oxidation mechanisms are therefore involved, resulting in different behaviors in terms of degradation and mineralization kinetics. While degradation only refers to the initial oxidation of PCT, mineralization involves a complete destruction of organic compounds into inorganic species. While results presented in section 3.1 and 3.2 gave information on the global mineralization effectiveness achieved, the objective of the following experiments was to emphasize the differences in electro-oxidation mechanisms ascribed to homogeneous oxidation in the bulk and heterogeneous oxidation at the  $\text{TiO}_x$  REM.

First, the evolution of both PCT ( $[\text{PCT}]_0 = 87 \text{ mg L}^{-1}$ ) and TOC concentrations ( $\text{TOC}_0 = 55 \text{ mg L}^{-1}$ ) was monitored over time when using REM and REM/EF configuration with continuous permeate recirculation (Fig. 4). With the REM configuration, it is interesting to observe that degradation and mineralization kinetics were very similar. This can be explained by the complete and fast mineralization of organic pollutants near the anode surface due to the production of large amounts of  $\text{M}(\cdot\text{OH})$  at the anode surface. Compared to plate anodes in batch experiments, the use of REM further favors the complete mineralization of organics since the oxidation process is focused on the small volume of solution passing through the REM, without back diffusion of molecules from the anode surface to the bulk. In fact, a single passage through the REM achieved 90% removal of TOC between permeate and retentate (Fig. 5). Besides, with the REM configuration, almost none oxidant species was generated in the retentate, thus avoiding PCT degradation in the retentate. Overall, the benefit of this configuration thus lies in the very low production and accumulation of degradation by-products that can be sometimes more toxic than initial molecules. Such phenomenon usually requires high current density for conventional plate anodes and results in low current efficiency because of mass transport limitations [7,26]. However, with this configuration, high MCE (24%) was maintained for 37% TOC removal thanks to the convection enhanced mass transport of pollutants towards the REM used as anode.

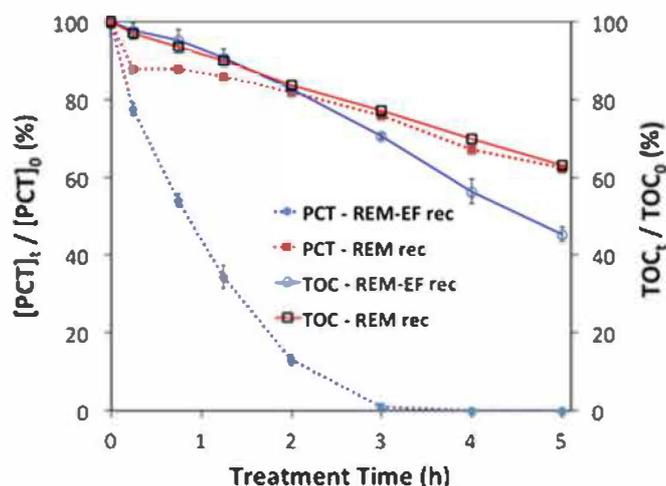

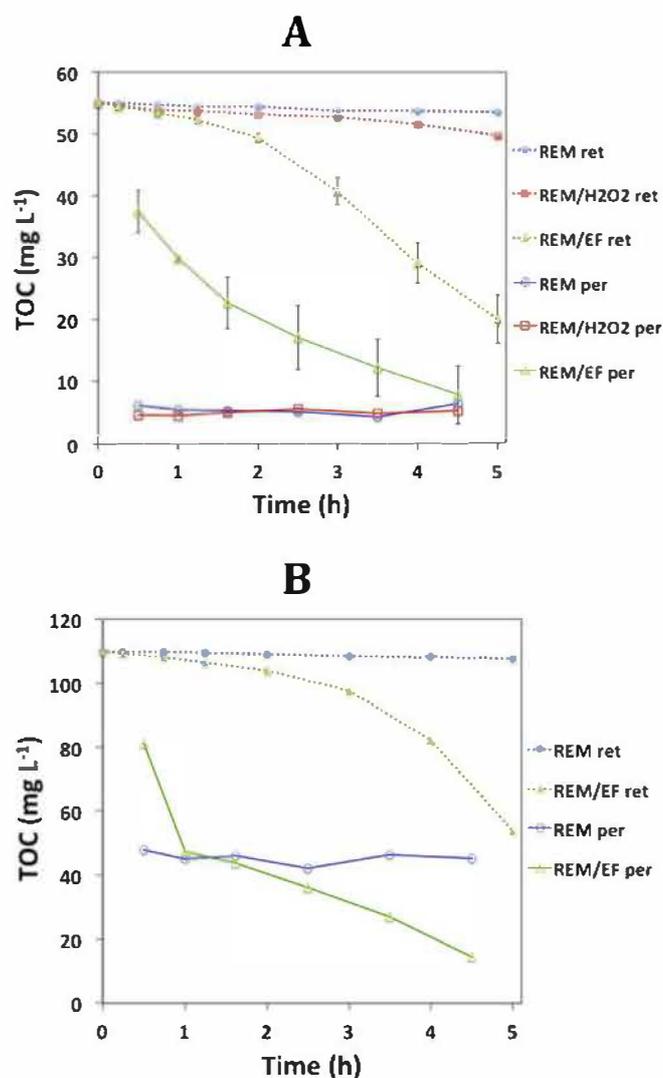

Fig. 4. PCT ( $[\text{PCT}]_0 = 87 \text{ mg L}^{-1}$ ) and TOC evolutions ( $\text{TOC}_0 = 55 \text{ mg L}^{-1}$ ) evolution over time, as a function of the experimental configuration (REM standalone process or integrated REM/EF process). All experiments have been performed with continuous recirculation of the permeate. Error bars for REM/EF have been calculated from replicate experiments ( $n = 3$ ). Calculations have been made using Eq. (5).

During the REM/EF process, faster degradation kinetic of PCT was observed compared to mineralization (Fig. 4). Data obtained for PCT degradation during the REM/EF process fit well with the pseudo-first order model ( $R^2 = 0.997$ ) with an apparent rate constant of  $0.84 \text{ h}^{-1}$ . In the previous study of Brillas et al. (2005), similar rate constant was obtained ( $0.78 \text{ h}^{-1}$ ) during AO using BDD anode. However, the current density was much higher ( $100 \text{ mA cm}^{-2}$  compared to  $15 \text{ mA cm}^{-2}$  in this study) and the ratio between the geometric surface area of the anode and the volume of solution was also higher  $0.030 \text{ cm}^{-1}$  (compared to  $0.0125 \text{ cm}^{-1}$  in this study). Homogeneous production of  $\cdot\text{OH}$  from electrochemically generated Fenton's reagent strongly improved the degradation of PCT in the retentate. In fact, > 99% of PCT was degraded after 3 h of treatment, while only 38% of PCT was degraded after 5 h of treatment by the REM process alone. Combination of REM with the EF process also increased the removal of TOC from 37 to 55% and the MCE from 24 to 35% after 5 h of treatment. The benefit of this configuration lies in the higher effectiveness for degradation and mineralization of PCT because of production of oxidant species both homogeneously in the bulk retentate and heterogeneously at the surface of the REM. Besides, the much faster degradation of PCT compared to the mineralization kinetic means that degradation by-products are accumulated in the solution. Recent studies have highlighted the possibility to combine the EF process with a biological post-treatment for cost-effective biodegradation of degradation by-products [46–49]. In this context, the REM/EF configuration would be much more suitable than the REM configuration.

Fig. 5A shows the evolution over time of TOC concentration in permeate and retentate during experiments with  $\text{TOC}_0 = 55 \text{ mg L}^{-1}$ . From TOC measurement in the retentate it is possible to observe electro-oxidation ascribed to homogeneous oxidation in the bulk, while heterogeneous oxidation at the REM can be observed from TOC removal between retentate and permeate. A similar trend was obtained for both REM and REM/ $\text{H}_2\text{O}_2$  configurations. TOC concentration decreased very slowly in the retentate because of the absence of homogeneous  $\cdot\text{OH}$  generation. Besides, the analysis of TOC in the permeate revealed that the effectiveness of the REM for PCT mineralization remained constant throughout the 5 h of treatment. In the case of the REM/EF integrated process, TOC concentration in the retentate decreased quickly due to the production of  $\cdot\text{OH}$  formed *via* Fenton's reaction (Eq. (2)). However, at the beginning of the experiment, the effectiveness of heterogeneous oxidation at the REM was lower in the

**Fig. 5.** TOC evolution over time, as a function of the experimental configuration (REM standalone process, REM/H<sub>2</sub>O<sub>2</sub> process, or integrated REM/EF process). (A) TOC<sub>0</sub> = 55 mg L<sup>-1</sup> and (B) TOC<sub>0</sub> = 110 mg L<sup>-1</sup>. All experiments have been performed without recirculation of the permeate. “ret” refers to concentrations analyzed in the retentate, while “per” refers to concentrations analyzed in the permeate. Error bars for REM/EF have been calculated from replicate experiments ( $n = 3$ ). Calculations have been made using Eqs. (5) and (6).

configuration REM/EF compared to the configuration REM alone (without generation of  $\cdot\text{OH}$  in the retentate). TOC removal at the REM by the REM/EF was only 32% at  $t = 0.5$  h of treatment with the REM/EF configuration, compared to 90% with the configuration REM. This phenomenon could be attributed to the promotion of wasting reactions at the REM surface during filtration of the retentate containing  $\cdot\text{OH}$  and  $\text{Fe}^{2+}$  in the case of the REM/EF configuration. These wasting reactions are more specifically (i) the dimerization reaction between  $\cdot\text{OH}$  homogeneously produced in the retentate and  $\cdot\text{OH}$  heterogeneously produced from AO at the REM (Eq. (13)) and (ii) the reaction of  $\cdot\text{OH}$  heterogeneously produced at the REM with  $\text{Fe}^{2+}$  ions present in the retentate (Eq. (14)).

Similarly, a lower effectiveness of the REM at the beginning of the treatment with the REM/EF process compared to the configuration with the REM alone was observed during experiments performed at initial TOC of 110 mg L<sup>-1</sup> (Fig. 5B). However, with this higher TOC concentration, the presence of  $\cdot\text{OH}$  and  $\text{Fe}^{2+}$  in the retentate had a lower impact on TOC removal by heterogeneously produced  $\cdot\text{OH}$  at the REM.

First, this phenomenon might be ascribed to a lower steady-state concentration of  $\cdot\text{OH}$  in the retentate because of further reaction of homogeneously generated  $\cdot\text{OH}$  with a greater amount of TOC. Furthermore, there is actually a competition between the different species in the retentate (organic compounds, homogeneously generated  $\cdot\text{OH}$  and  $\text{Fe}^{2+}$ ) for reaction with heterogeneous  $\cdot\text{OH}$  generated at the REM. By increasing the TOC concentration in the retentate, the reaction between heterogeneous  $\cdot\text{OH}$  and organic compounds might be promoted, thus decreasing wasting reaction of heterogeneous  $\cdot\text{OH}$  with  $\text{Fe}^{2+}$  and homogeneously generated  $\cdot\text{OH}$ .

Interestingly, with the REM/EF configuration, it was observed that the reaction in the retentate strongly improved the effectiveness of the heterogeneous reaction at the REM. For example, during the experiment with TOC<sub>0</sub> = 55 mg L<sup>-1</sup>, TOC removal by the REM increased from 32% at  $t = 0.5$  h to 57% at 1.6 h of treatment (values calculated from TOC data given in Fig. 5; details of these results are provided as Supplementary Material), while TOC removal in the retentate was less than 10% in the same time. Even more significant, during the experiment at TOC<sub>0</sub> = 110 mg L<sup>-1</sup>, TOC removal by the REM increased from 26% at  $t = 0.5$  h to 59% at  $t = 1.6$  h, while TOC removal in the retentate was less than 6% in the same time. These results indicate a strong synergistic effect between the EF process and the use of TiO<sub>x</sub> REM as anode. The EF process is well known for producing rapidly short-chain carboxylic acids as degradation by-products of aromatic organic pollutants, particularly oxalic and oxamic acids in the case of PCT [50]. In this study, oxamic acid was used as a model molecule for carboxylic acid compound in order to assess the fate of such components. A high concentration of 23 mg L<sup>-1</sup> was detected in the retentate after 5 h of treatment with the REM/EF configuration (TOC<sub>0</sub> = 55 mg L<sup>-1</sup>). By comparison, only 2.5 mg L<sup>-1</sup> of oxamic acid was detected in the permeate with the REM configuration (same TOC<sub>0</sub>). Compared to aromatic compounds, carboxylic acids have lower rate constants for reaction with  $\cdot\text{OH}$  homogeneously produced in the bulk. However, TiO<sub>x</sub> REM is able to quickly oxidize such compound by direct electron transfer [29,30]. Therefore, when using TiO<sub>x</sub> REM as anode, both  $\cdot\text{OH}$ -mediated oxidation and direct electron transfer can occur simultaneously [27,29,30]. Thus, such anode material is particularly suitable for improving the removal of carboxylic acids and the mineralization efficiency of the EF process.

The antagonist and synergistic phenomena occurring during the combination of homogeneous electro-oxidation (in the bulk retentate by electrochemically produced Fenton’s reagent) and heterogeneous electro-oxidation (at the TiO<sub>x</sub> REM by AO) is highlighted for the first time in this configuration allowing the separation of oxidation mechanisms in the bulk retentate and at the anode/REM.

#### 4. Conclusions

Optimal conditions for removal of PCT (TOC<sub>0</sub> = 55 or 110 mg L<sup>-1</sup>) by the REM/EF integrated process were selected as (i)  $j = 15$  mA cm<sup>-2</sup> (ii) recirculation flow rate of 1 L min<sup>-1</sup> involving TMP = 30 mbar and  $J = 95$  L h<sup>-1</sup> m<sup>-2</sup> and (iii) continuous O<sub>2</sub> supply. Very high efficiency of this process was obtained for mineralization of PCT solution (e.g., 59% removal of 110 mg L<sup>-1</sup> of TOC with MCE = 77%) because of favorable mass transport conditions for (i) H<sub>2</sub>O<sub>2</sub> production owing to the flow-through operation mode with continuous recirculation of the retentate through the CF cathode and (ii) electro-oxidation of organic compounds at the TiO<sub>x</sub> REM owing to the convection-enhanced mass transport of pollutants during filtration through the REM. Such conditions allow taking advantage of the high electro-active surface area of these three dimensional porous electrodes.

The configuration REM/EF allowed for the first time the separation of oxidation mechanisms in the bulk retentate and at the anode/REM. An antagonist effect was observed during filtration of the bulk retentate through the REM because of wasting reactions of  $\cdot\text{OH}$  heterogeneously produced at the REM with  $\cdot\text{OH}$  homogeneously produced in the

retentate as well as with  $\text{Fe}^{2+}$  ions. However, a strong synergistic effect was also emphasized between the degradation of PCT in the retentate by homogeneous  $\cdot\text{OH}$  and the complete mineralization of degradation by-products at the REM. In fact, direct electron transfer can also occur at the  $\text{TiO}_x$  REM and degradation by-products such as carboxylic acids are more easily mineralized by direct electron transfer than by oxidation with homogeneous  $\cdot\text{OH}$ . This phenomenon also explains why the overall efficiency of the REM/EF integrated process far exceeded the efficiency of EF and REM used as standalone processes.

### Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

### Acknowledgements

We gratefully acknowledge the National French Agency of Research 'ANR' for funding the project ECO-TS/CElectrON (ANR-13-ECOT-0003). Clément Trellu particularly thanks the agency for post-doctoral fellowship. Authors are also grateful to Saint-Gobain Research Provence (CREE Cavaillon France) for supplying reactive electrochemical membranes in the framework of the ANR program.
