ABSTRACT

Background: There is little data on major muscular hematomas and the little there is has mainly focused on patients exposed to oral anticoagulants.

Objective: To describe the clinical characteristics, management and outcomes of patients admitted to emergency department (ED) for major muscular hematoma associated with an antithrombotic agent, and to identify predictors of in-hospital mortality.

Patients and Methods: Over a three-year period, all consecutive cases of adult patients admitted to the ED of 5 tertiary care hospitals for major muscular hematoma while exposed to an antithrombotic agent were prospectively collected and medically validated. Clinical and biological data, therapeutic management of the bleeding event, and in-hospital mortality were collected from the medical records and compared across five groups of hematoma locations. Potential confounders were taken in account using a multivariate binomial regression model.

Results: Three hundred and seventy-five patients were included (mean age = 81.4 years): 271 were exposed to vitamin K antagonists, 58 to parenteral anticoagulants (heparin, LMWH, fondaparinux), 33 to antiplatelets, and 13 to direct oral anticoagulants. The muscular hematomas were located in the lower limbs (n = 198), the rectus sheath (n = 71), the iliopsoas (n = 45), the upper limbs (n = 33), or elsewhere (n = 28). Reversal therapy was prescribed for 48.5% of patients, red cell transfusions for 63.6%, surgery for 12.3% and embolization for 3.5%. For 84% of patients, hospitalization was required, with a median length of stay of 10 days. Overall, in-hospital mortality was 8.5%. Reversal therapy, the need for intensive care and mortality were significantly more frequent among patients with iliopsoas hematomas. The independent predictors of in-hospital mortality were: decrease in mean arterial pressure (RR = 1.84), decrease in hemoglobin level (RR = 1.37) and the iliopsoas location (RR = 3.06).

Conclusion: Frail elderly patients with major muscular hematomas linked to antithrombotic agents risk substantial morbidity and in-hospital mortality. The iliopsoas location was the most life-threatening bleeding site. Close observation of this population is warranted to ensure better outcomes.

1. Introduction

Major bleeding is the most feared complication among patients exposed to antithrombotic agents. Most studies have focused on the two main bleeding complications, gastrointestinal bleeding and intracranial hemorrhage [1-4]. Few studies have reported on major muscular hematomas [5]. There is sparse, imprecise data on the incidence, morbidity and mortality of muscular hematomas associated with antithrombotic agents. In a 2-year study including 913 patients consecutively admitted to our emergency department with major bleeding associated with antithrombotic agents, muscular hematomas were observed for 86 patients (9.4%), of whom 66.3% were exposed to oral anticoagulants, 19.8% to antiplatelet agents and 13.9% to parenteral anticoagulants; a one-month mortality of 4.5% was observed [6]. Most studies have reported on muscular hematomas irrespective of severity and have mainly focused on patients exposed to oral anticoagulants. In a study by Xu *et al.* [7] including 1542 patients with bleeding linked to oral anticoagulants, muscular hematomas without compartment syndrome were reported for 82 patients (5.3%) exposed to warfarin, and for 8 patients (1.7%) exposed to direct oral anticoagulants (DOAC). Green *et al.* [8] reported musculoskeletal bleeding for 10% of patients exposed to oral anticoagulants. In an Italian cohort of 806 patients with major bleeding while exposed to vitamin K antagonist (VKA) or DOAC, soft-tissue bleeding accounted for 11% of VKA-exposed patients and 6% of DOAC-exposed patients [9]. In a prospective multicenter study on major bleeding related to VKAs, deep-muscle hematomas accounted for 13% of bleeding events with a 7-day mortality of 4% [10]. Finally, in another study, among 80 patients on anticoagulants with spontaneous soft-tissue hemorrhage including muscular hematomas, most required transfusion, aggressive resuscitation, reversal therapy, or embolization and one-month mortality reached 11% [11].

Over a three-year period, we conducted a prospective population-based cohort study named SACHA collecting all major bleeding events occurring among patients exposed to antithrombotic agents (nearly 98,000 person-years of exposure) whatever the indication, and referred to emergency department [12,13]. The SACHA study included 6484 patients with major bleeding events, among whom 2090 (32.2%) presented major bleeding other than gastrointestinal or intracranial hemorrhages. Of these, 375 had major muscular hematomas, amounting to 5.8% of the overall population included.

Our primary objective was to describe the clinical characteristics and the management of these 375 patients referred to emergency departments for major muscular hematomas associated with antithrombotic agents. Our secondary objective was to identify risk factors for in-hospital mortality.

2. Materials and Methods

2.1. Study design and participants

The SACHA study is a French prospective population-based multicenter cohort study on the incidence and outcome of major bleeding among patients exposed to antithrombotic agents whatever the type (parenteral or oral anticoagulant, or antiplatelet agent) or the indication [12,13].

For the current analysis, all consecutive adult patients admitted between January 1, 2013 and December 31, 2015 to the emergency departments of five tertiary care hospitals for major, acute muscular hematoma while exposed to an antithrombotic agent were included in the analysis. The severity of the bleeding was defined from at least one of the following criteria [14]: unstable hemodynamics (systolic arterial pressure < 90 mmHg or mean arterial pressure < 65 mm Hg) or hemorrhagic shock, uncontrollable bleeding, need for transfusion or hemostatic procedure (embolization, surgery) and compartment syndrome. In each emergency department, the local referent medical doctor validated the final inclusion of all records screened for acute, severe bleeding. The following patients were excluded from the analysis: patients with muscular hematomas occurring during hospitalization after admission for reasons other than bleeding, and patients hospitalised for an intentional overdose of antithrombotic drugs.

No informed signed consent was required. The study was reviewed and approved by the Rennes University Hospital Review Board and received regulatory approval (CNIL, DR-2013-488, with subsequent substantial changes DR-2016-489); ClinicalTrials.gov identifier: NCT02886533.

2.2. Data source and variables

From the emergency department clinical records, clinical and biological data were collected: demographics (age, gender), medical history, history of trauma, comorbid conditions, antithrombotic agent class (oral anticoagulants (VKA or DOAC), parenteral anticoagulants (heparin, low-molecular-weight heparin, fondaparinux), antiplatelet agents (mono or dual therapy) and any combinations), the indications for the antithrombotic agents, the type of bleeding/outcome, vital signs at admission (mean blood pressure), biological data at admission (hemoglobin and creatinine levels), management of the bleeding in the emergency department: specific emergency therapies such as red blood cell transfusion, platelet transfusion, plasma transfusion, vitamin K, protamin sulfate, prothrombin complex concentrates (PCC) and FEIBA, and vascular or surgical procedures. From hospital medical

records, the length of stay in hospital and in ICU, and fatalities defined as in-hospital mortality were extracted.

2.3. *Statistical analysis*

Firstly, the clinical characteristics were described according to hematoma locations divided into 5 groups: upper limb hematoma, lower limb hematoma, rectus sheath hematoma, iliopsoas hematoma, and others. The distribution of antithrombotic agent classes - oral anticoagulants (vitamin K antagonist, direct oral anticoagulant), antiplatelet agents (monotherapy or dual therapy), and parenteral anticoagulants (heparin, low molecular weight heparin (LMWH), fondaparinux) – was studied across hematoma locations.

Secondly, management and in-hospital mortality were compared across hematoma locations.

For the stratified statistical analysis, general association statistics were used, testing the alternative hypothesis that, for at least one stratum, there is some kind of association. Potential confounders were then taken in account in a multivariate binomial regression model. All statistical tests were two-tailed and P-values <0.05 were considered significant. Statistical analyses were performed using SAS software 9.4 (SAS Institute, Cary, N.C., USA).

3. Results

3.1. Clinical characteristics

Over a 3-year period, 375 patients (mean age 81.4 years) with major muscular hematomas were included; 56.3% were female; 293 patients (78.1%) met the ISTH criteria [15]. Among the remaining 82 patients, 41 had either unstable hemodynamics, hemorrhagic shock, or uncontrollable bleeding. Patient enrolment was based on medical validation.

Table 1 shows the clinical characteristics, comorbidities, and biological data recorded at admission according to hematoma location. The distribution of muscular locations was as follows: lower limb hematoma (n = 198), rectus sheath hematoma (n = 71), iliopsoas hematoma (n = 45), upper limb hematoma (n = 33), other locations (n = 28, including gluteal n = 6, latissimus dorsi n = 5, pectoralis n = 5, miscellaneous n = 3, and non-determined n = 9). A history of trauma was reported for about half of the population, especially among patients with limb hematomas. Ground-level falls were the predominant cause of injury.

The distribution of antithrombotic agents according to hematoma location is shown in Appendix A **Table A.1**. For three quarters of the patients (284/375, 75.7%), muscular hematomas were associated with oral anticoagulants, mostly VKAs (n = 271, 95.4%) rather than DOACs (n = 13, 4.6%).

The indications for antithrombotic agents are reported in Appendix A **Table A.2**. The main indication for oral anticoagulants was atrial fibrillation (AF) (60.5% for VKA and 69.2% for DOAC) followed by venous thromboembolism (VTE). Antiplatelet agents were prescribed to patients with stroke and coronary disease.

3.2. Management of the bleeding event

For the entire population, reversal therapy (vitamin K and/or PCC) was prescribed to 182 (48.5%) patients (Appendix A **Table A.3**). Red blood cell transfusions were required for 235 (63.6%) patients. For 46 (12.3%) patients, surgery was required for compartment syndrome. Thirteen (3.5%) required embolization. Hospitalization was required for 84% of the overall population with a median length of stay of 10 days.

Appendix A **Table A.4** shows the management of the bleeding event among patients receiving VKAs according to hematoma location. Reversal therapy using vitamin K or PCC was prescribed more often to patients with iliopsoas hematomas than to patients with other hematoma locations (p= 0.005). Red blood cell transfusions were needed for 60% of the overall population. For 14 patients with lower limb hematoma and 9 patients with upper limb hematoma, surgery was required for compartment syndrome.

Table 1

Baseline characteristics according to hematoma location. Values are Frequency (Percent), or mean $\pm$ SD, MAP stands for Mean arterial pressure, GI for gastrointestinal, and IC for intracranial. P-value based either on chi-square test, Fisher's exact test or Kruskal-Wallis' test.

3.3. Predictors of in-hospital mortality

Overall in-hospital mortality was 8.5%, higher among patients with iliopsoas hematoma than among patients with other hematoma locations ($p = 0.015$) (Appendix A **Table A.5**). The univariate and multivariate analyses for predictors of in-hospital mortality are reported in **Table 2**. Age, gender, hematoma location, reversal therapy, surgery, embolization, class of antithrombotic agents, trauma, and biological data at admission were variables used in the univariate analysis. Iliopsoas hematoma (RR = 3.06, 95%CL: 1.69-6.73), a 20-unit decrease in mean arterial pressure (RR = 1.84, 95%CL: 1.20-2.82) and a 2-unit decrease in hemoglobin level (RR = 1.37, 95%CL: 1.06-1.77) were the 3 independent predictors of in-hospital mortality.

Table 2

Predictors of in-hospital mortality (univariate analysis based on 375 observations and 32 deaths, multivariate analysis based on 361 observations). ¹ vitamin K, prothrombin complex concentrate (PCC), plasma transfusion or protamin sulfate; DOAC stands for direct oral anticoagulant, Hb for hemoglobin, MAP for mean arterial pressure, RR for risk ratio, and CL for confidence limit.

4. Discussion

Our population was a large prospective cohort of 375 patients who had been prescribed some type of antithrombotic agent and who had been referred for major muscular hematomas. To include a population that was as homogenous as possible, strict criteria were used to define major bleeding, based on the French guidelines [14]; however, we acknowledge that there was a slight alteration with respect to the International Society on Thrombosis and Hemostasis (ISTH) classification [15]. This selected cohort corresponded to nearly half of the overall population exposed to antithrombotic agents with intramuscular hematoma, in line with Moustafa *et al.*, who reported major muscular bleeding using the ISTH criteria for about half of his recruitment [5]. A large majority of the major muscular hematomas observed in this study were associated with oral or parenteral anticoagulants (91.2%). Major muscular hematomas have been very rarely associated with antiplatelet agents, 8.8% in the present study and 4% in our previous study [6], irrespective of location. Indeed, only case-reports of patients with major muscular hematoma associated with antiplatelet agents were found [16-20].

Except for iliopsoas hematomas, major muscular hematomas have been reported to occur particularly among older women [21]. Trauma was reported in about half of this population, especially in the limbs, with a large predominance of ground-level falls. In our study, spontaneous hematomas were observed in rectus sheath and iliopsoas locations, which is in line with other studies [22,23].

The lower limbs are the main hematoma location. Most are post-traumatic and more than four-fifths of the patients require hospitalization. In our cohort, 14 patients (11%) required surgical decompression and fasciotomy. This well-known complication is most common in the anterior and deep compartments of the leg [24,25]. Upper arm hematomas were observed for 33 patients (9%). For 9 patients exposed to VKAs, surgery was required for compartment syndrome, which is an uncommon bleeding complication rarely reported in the literature. Indeed, Maeckelbergh *et al.* found only 13 articles reporting cases of upper arm compartment syndrome in a review of the literature [26]. Early surgery for decompression (fasciotomy) is essential to prevent irreversible muscle ischemia, tissue necrosis, permanent functional impairment and in some cases renal failure due to rhabdomyolysis [27].

Almost all patients with rectus sheath hematoma (RSH) in our study were exposed to oral or parenteral anticoagulation. RSHs have been reported among patients exposed to subcutaneous heparin and LMWH injections for atrial fibrillation or venous thromboprophylaxis, with an increased risk in the elderly population [28]. Invasive hemorrhage control should be

considered in case of unstable hemodynamics or signs of abdominal compartment syndrome: angiography, and embolization or surgical ligation of bleeding vessels, have been reported to be safe and efficacious [29,30].

Although uncommon, the most serious hematoma location is iliopsoas hematoma [22,23,31,32]. In the present study, 84.4% of these patients were exposed to oral anticoagulants and 13.3% to parenteral anticoagulants. This location combined all severity criteria: the most severe clinical presentations, unstable hemodynamics, hemorrhagic shock, increased creatinine levels, and high in-hospital mortality (22.2 %). Among patients receiving VKAs, reversal therapy with vitamin K and PCC was required for 75.7% and 56.8% respectively; surgery and embolization were required for 10.8% and 5.4% respectively. These elements are in line with Ljitos *et al.*, who reported on 77 patients with iliopsoas hematoma in 3 ICUs over an 8-year period [23]. Most of them were exposed to anticoagulants (72%), some required reversal therapy (38%), and 22% and 9% respectively required embolization or surgery, with a high mortality of 30%. As reported in the present study, the majority of iliopsoas hematomas (here 35/45) are spontaneous [22,33]. Patients with a combination of antithrombotic agents, such as heparin plus vitamin K antagonist or vitamin K antagonist plus antiplatelet agent, have been reported to be more likely to require intensive care and a longer ICU stay [34]. Iliopsoas hematoma is a potentially life-threatening site of bleeding leading to a mortality rate of 20 to 30% [23,31].

No statistical comparison between oral anticoagulants was performed, because our study was not designed for this, but previous results suggest that DOACs are associated with a lower proportion of “other” major bleeding (including muscular hematomas which account for 1/3 of these events) [13].

In our cohort of cases of major intramuscular bleeding, in-hospital mortality was significant (8.5%). Neither age, the type of antithrombotic agent nor specific reversal therapy were predictors of mortality. Compared to other locations, the iliopsoas location was a strong predictor of mortality, which is in line with other authors' findings [31,34].

In conclusion, in our study lower limb hematomas were the most frequent location, but the iliopsoas location was the most life-threatening bleeding site. Decreases in mean arterial pressure and in hemoglobin levels and the iliopsoas location were independent predictors of mortality. Physicians should be aware that intramuscular hematomas associated with antithrombotic agents can lead to significant morbidity and mortality. Close observation is warranted for these patients to ensure better outcomes.

Declaration of interests

☒ The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

☐ The authors declare the following financial interests/personal relationships which may be considered as potential competing interests:

Data on major muscular hematomas while exposed to any antithrombotic agents are lacking

Major muscular hematomas were mostly located in the lower limbs

Iliopsoas location was an independent predictor of in-hospital mortality
