Abstract

Using the *in silico* experimental evolution platform Aevol, we have tested the existence of a “complexity ratchet” by evolving populations of digital organisms under environmental conditions in which simple organisms can very well thrive and reproduce.

We observed that in most simulations, organisms become complex although such organisms are a lot less fit than simple ones and have no robustness or evolvability advantage. This excludes selection from the set of possible explanations for the evolution of complexity. However, complementary experiments showed that selection is nevertheless necessary for complexity to evolve, also excluding non-selective effects.

Analyzing the long-term fate of complex organisms, we showed that complex organisms almost never switch back to simplicity despite the potential fitness benefit. On the contrary, they consistently accumulate complexity on the long term, meanwhile slowly increasing their fitness but never overtaking that of simple organisms. This suggests the existence of a complexity ratchet powered by negative epistasis: mutations leading to simple solutions, that are favourable at the beginning of the simulation, become deleterious after other mutations — leading to complex solutions — have been fixed. This also suggests that this complexity ratchet cannot be beaten by selection, but that it can be overthrown by robustness because of the constraints it imposes on the coding capacity of the genome.

Keywords: *in silico* experimental evolution, complexity, epistasis, robustness, evolvability.

1 Introduction

Despite decades of deep interest by different scientific communities (including artificial life, population genetics, computational biology and, of course, evolutionary biology), the question of the evolutionary origin of biological complexity is still controversial. While there is a general agreement — tempered by the recognition that complexity has decreased in some organisms [4] — that biological complexity has globally increased during geological time, there is no general agreement on whether or not this is a general trend [19]. But the most discussed point is the ultimate causes of complexity increase. Roughly, two classes of theories are competing to explain this increase: those based upon selection and those invoking the variation process itself. According to theories of the former class, complexity rises because complex organisms are more likely to outcompete simple ones in a demanding environment (but the precise mechanisms vary among the authors). For theories belonging to the latter class, complexity is rooted in the properties of the variation process that is supposed to be biased toward an increase in complexity (there again, the origin of the bias varies among the authors). Artificial Life has provided many examples of the former [2, 35]. A famous tenant of the latter is Stephen Jay Gould who proposed that, since complexity has a lower bound, it can only increase through a random variational process (the “drunkard’s walk” model), hence the observed trend [12]. Following a similar “neutral” hypothesis, Soyer and Bonhoeffer proposed that the complexification trend is due to duplication being less deleterious than deletion, an unbiased mutational process hence being likely to produce increasingly complex organisms on the long run [30]. More recently, Brandon and McShea have proposed the “Zero-Force Evolutionary Law” (ZFEL, [21]) stating that *“In any evolutionary system in which there is variation and heredity, there is a tendency for diversity and complexity to increase, one that is always present but may be opposed or augmented by natural selection, other forces, or constraints acting on diversity or complexity”* ([21], chapter 1, page 4). According to the authors, the ZFEL spontaneously pushes evolving systems toward an increase in diversity and complexity even in the absence of selection and even when the mutational process is unbiased or when the considered system is far from its lower complexity bound, making it a strong universal mechanism.

There are many reasons why evolution of complexity is controversial [22]. Two of them are central: First, the lack of universally accepted measure of complexity (although an elegant way to bypass this difficulty has been proposed by Adami who considers complexity as equivalent to the quantity of information an organism integrates about its environment [1]); Second, biological organisms are multi-scale systems that can increase their complexity — or not — at different organization levels or even increase

— or decrease — the number of organization levels (*i.e.* horizontal and vertical complexity respectively [20]). A striking example is the strong loss of complexity undergone by endosymbionts that is directly linked to the emergence of a new system through the association of an eukaryote and a bacterium [4]. Even when considering single organisms, there is no reason to suppose that the variations in complexity (or quantity of information) are homogeneous across the genome/transcriptome/proteome/phenotype levels: some well known paradoxes such as the C-Value paradox [31] and the G-Value paradox [13] illustrate the fact that the quantity of information encoded in the genome may not be linked to the quantity of information at the phenotypic level. Hence, while most models used to investigate the evolution of complexity focus on a single organization level, it is necessary to consider the evolution of complexity at a given level in the context of the complexity needed at higher levels. Following this idea, in order to investigate whether or not the complexity increase is selected, one has to use a multi-scale model and let organisms evolve in an environment requiring only a simple phenotype (hence excluding the selective hypothesis). By observing whether this simple phenotype will be encoded by a simple or a complex functional organization, it is then possible to distinguish between passive and active trends towards complex structures.

Here we used the Aevol model [14, 15, 5] to implement this research program. Aevol is a digital evolution platform in which organisms are encoded at the genome level but with a decoding procedure directly inspired from the biological genotype-to-phenotype mapping and an abstract description of the functional levels (proteins and phenotype). Since this decoding procedure includes many degrees of freedom, Aevol allows the different organization levels (typically genome, proteome and phenotype) to evolve different degrees of complexity. For instance a simple phenotypic function can be encoded either by a combination of many different genes or by one single gene. Similarly, the genome can evolve to be more or less compact depending on the amount of non-coding sequence and depending on the sharing of sequences among multiple genes by *e.g.* operons or gene overlapping. This decoupling of complexity among the different organization levels makes Aevol perfectly suited to study the evolution of complexity. In the experiments described here, we used a slightly modified version of the model in which the environment allows for very simple organisms to thrive. We then studied a very large number of evolutionary trajectories to test whether or not these trajectories show an increase in complexity. Our results show that even though simple organisms are likely to have a higher fitness than complex ones, most lineages show a long-term increase in complexity during evolution. This suggests that even in simple environments there is a “complexity ratchet” that cannot be beaten by selection. We also

show that, contrary to a widespread intuition, complex organisms are not more evolvable or more robust than simple ones and that, when selection is removed, all organisms quickly loose complexity, excluding the ZFEL from the set of possible candidates to explain the complexity trend observed in our experiments. Finally, our results show that while selection is not powerful enough to drive evolution toward simplicity, the need for mutational robustness is: when a complex organism experiences an increase in its mutation rate, its complexity is very likely to decrease, ultimately switching to a simple structure.

This article is an extended version of V. Liard, D. Parsons, J. Rouzaud-Cornabas, and G. Beslon (2018) The complexity ratchet: Stronger than selection, weaker than robustness. In: Proceedings of the Artificial Life Conference, Tokyo (Japan), July 2018, MIT Press, pages 250-257 [17].

2 Methods

2.1 The Aevol model

Aevol (www.aevol.fr and references therein) is an *in silico* experimental evolution platform developed by the INRIA Beagle team (<https://team.inria.fr/beagle>). Figure 1 presents an overview of the model. Since Aevol has been extensively described in previous publications, we only describe its basic organization and focus on the structure of the information coding as it is at the core of our experiments.

2.1.1 Overview

The rationale of Aevol is that the structure of the fitness landscape of an organism is likely to be strongly determined by the structure of the biological information coding of this organism. Hence, Aevol mimics precisely the biological genomic structure as well as the structure of genotype-to-phenotype mapping. Organisms are then embedded in an evolutionary loop that includes classical selection operators and a large variety of mutational operators including base switch (flipping the bits on both strands), small insertions and small deletions (aka. InDels) and large scale chromosomal rearrangements (duplications, deletions, inversions and translocations). All mutation operators have their own rate expressed in $\text{mutations.base-pair}^{-1}.\text{generation}^{-1}$ ($\text{mut.bp}^{-1}.\text{gen}^{-1}$).

Figure 1: The Aeol model. (A) Overview of the genotype-to-phenotype map. Note that the organism shown here is a real organism evolved within Aeol for 200,000 generations with a typical Aeol target (see main text and Figure 2 for the target used in the experiments presented here). Hence it contains many genes on both strands (left panel), many proteins (central panel) and it is well adapted to its environment (*i.e.* its phenotypic function — black curve on the right panel — is very close to the target function — light red plain curve). (B) Population on a grid and evolutionary loop. (C) Local selection and replication processes occur within a Moore neighborhood. (D) Variation operators include chromosomal rearrangements (duplications, deletions, translocations and inversion — here a translocation and an inversion are shown) and local mutations (switches and InDels).

2.1.2 Information coding in Aevol

In Aevol, each individual owns a genome containing its heritable information. The genome is a binary double-strand sequence. It is decoded in two steps: *Transcription* and *Translation*. The transcription process relies on consensus signals (promoters) and hairpin-like structures (terminators) for transcription initiation and termination respectively. The translation process involves consensus Ribosome-Binding-Sites (RBS) and an artificial genetic code based on triplet codons (including START and STOP codons). The sequence of codons of a gene then constitutes the primary structure of a protein. Importantly, this decoding process introduces degrees of freedom between the genome and the proteome: complex genomes can encode for simple proteomes (*e.g.* if all genes have the same sequence) and complex proteomes can be encoded on small sequences (if genes share sequences through *e.g.* polycistronic mRNAs or overlapping genes). These degrees of freedom are similar to those found in real organisms.

Given the primary structure of a protein, Aevol computes its functional contribution. Although mimicking biological processes at the sequence level is feasible, it is — at least to date — impossible to compute the function of a protein from its primary structure in a realistic way. That is why Aevol uses an abstract mathematical formalism to describe the functional levels (*i.e.* protein functional contribution and phenotype). In Aevol all functions are expressed in a one-dimensional continuous “functional space” (more precisely on the $[0, 1]$ interval) by an activation value in the $[-1, 1]$ interval (upper and lower bounds corresponding to maximum activation and maximum inhibition respectively). In this space, proteins are described as isosceles-triangle-shaped kernel functions. These triangles can themselves be described by three parameters (their mean m , height h and half-width w) which are computed from three interlaced variable-length binary codes in the primary structure of the protein (hence the longer the gene the more precise the m , w and h values). Once all the kernels have been computed from the protein set (Figure 1.A, center), they are summed to compute the phenotype (Figure 1.A, right). Just as the transcription-translation process introduces degrees of freedom between the genome and the proteome, this step introduces degrees of freedom between the proteome and the phenotype. Indeed, the combination of different proteins can result in a simple functional shape *e.g.* if the proteins share the same m and w values (see *Complexity measures* section below).

Finally, in Aevol, the fitness is computed as the exponential of the difference between the phenotypic function and a target function indirectly representing the abiotic conditions the organisms evolve in (in light red on Figure 1.A, right). Classically in Aevol the target function is defined by a sum of Gaussians, hence requiring a virtually infinite number of triangular kernels to be perfectly fit. In the

experiment described here, we used a modified version of Aevol (code available at http://www.aevol.fr/publications/ressources/Liard2018_ALife_src.tgz) in which the target function is described by triangles, hence being perfectly fittable by the phenotype (see below).

2.2 Experimental design

In order to test whether evolution has a spontaneous tendency to increase complexity or whether the complexity increase is due to the environmental pressure, we let evolve populations of 1,024 individuals in Aevol in a null model where the environment is so simple that it does not require a complex proteome nor a complex genome. To this aim, we designed an environmental target which shape is an isosceles triangle (Figure 2.A — to be compared to the classical environment used in Aevol experiments, Figure 1.A, light red filled curve). Hence, the target can be fitted by a single protein and thus a single gene. More precisely, the target is an isosceles triangle with mean $m = 0.5$, height $h = 0.5$ and half-width $w = 0.1$. Note that although this target can be fitted with a single gene, it is still hard to fit since it requires that the corresponding gene be long to get enough precision (see the description of the model above).

All simulations are initialized with a random 5,000 bp genome containing at least one functional gene. We tested three mutation rates: $\mu = 10^{-4}$, $\mu = 10^{-5}$ and $\mu = 10^{-6}$ mut.bp⁻¹.gen⁻¹. Note that we also tested $\mu = 10^{-7}$ mut.bp⁻¹.gen⁻¹ but evolution was too slow for the data to be usable on 270,000 generations only. Each population evolved for 270,000 generations. We then reconstructed the lineage of the best final individual and the statistics of the fitness, genome size, number of genes and structure of the protein network along this line of descent from generation 0 to generation 250,000 (*i.e.* all statistics are recorded on common ancestors of the final population — the last 20,000 generations being ignored because, due to coalescence time, there no such thing as a fixed lineage when getting too close to the final generation). We then repeated the experiment 100 times for each mutation rate for a total of 300 simulated evolutions.

2.3 Complexity measures

Generally speaking, there is no consensus on complexity measures. Moreover, since Aevol is a multiscale model, one has to choose different measures at the different levels (*i.e.* different measures of horizontal complexity [20]; vertical complexity — the number of levels — being constant in the model). Typically here we will measure complexity at the sequence level — the genome — and at the functional level

Figure 2: (A) Phenotypic target used during the experiment. (B, C) Genome (top, black arcs represent the coding segments — the genes — on both strands of the circular chromosome) and proteome (bottom, red dashed line indicates the target function and black triangles indicate the proteins function) of a simple (B) and a complex (C) individual (both evolved exactly in the same conditions; $\mu = 10^{-5}$ mut.bp $^{-1}$.gen $^{-1}$). (D) Zoom on the proteome of the complex individual shown in (C).

— the proteome (complexity is not measured at the phenotypic level since it is directly driven by selection which imposes that this level remain as simple as possible). We thus adopted two strategies. First, we adapted principles from [2] to Aevol in order to get quantitative measures at the genome and proteome levels by estimating the quantity of information stored in both structures. Second, we designed a qualitative classification of *Simple* vs. *Complex* organisms based upon the structure of the model.

2.3.1 Quantitative measure at the sequence level

Aevol provides numerous statistics on the lineage of a given organism. In particular, it provides statistics about the number of “essential” base pairs (*i.e.* base pairs which, if mutated, change the phenotype of the organism). Hence, this measure can be directly used to estimate the quantity of information stored on the genome *i.e.* the genome complexity $\mathcal{C}_G$. Note that it may be very different from the genome size since the genome can accumulate non-coding sequences. It can also be shorter than the sum of gene lengths since genes can share sequences through gene overlapping on the same strand or on the opposite strand (see Figure 2.C for examples of overlapping genes).

2.3.2 Quantitative measure at the functional level

While measuring complexity on the genome is relatively straightforward, measuring complexity at the proteome level (*i.e.* functional complexity) is a more difficult. Indeed, in a first approximation, one could consider that the proteome complexity is given by the number of non-degenerated proteins¹. However, since different proteins can perform similar functions (*e.g.*, in case of gene duplication), this would overestimate the quantity of information contained in the proteome. Hence, we considered proteome information in a more precise way by estimating the number of different parameters in the proteome. $\mathcal{C}_P$, the functional complexity measure, is then the sum of the number of different m , different w and different h values (all with a small tolerance $\varepsilon = 0.001$ to account for rounding errors) used to encode the protein set. Note that this definition of functional complexity is close to the Brandon and McShea’s notion of “pure complexity” (*i.e.* number of different part types within an organism [21]).

¹Degenerated proteins encode for triangles which area is equal to zero (*i.e.* $h = 0$ and/or $w = 0$). These proteins hence don’t contribute to the phenotype.

2.3.3 Qualitative classification

To study the long-term fate of simple vs. complex organisms, we defined a qualitative classification procedure. Since the environmental target constrains the phenotypic level, the phenotypic function cannot be used to classify the organisms. We then chose to classify organisms according to their functional structure, hence focusing on the proteome level. A simple solution would have been to define a threshold on the quantitative measure but this threshold would be arbitrary. To avoid this, we used knowledge from the model structure to define the two classes. In Aevol, if all the non-degenerated proteins of an organism have the same mean m and the same half-width w , then their functions linearly sum-up to produce a triangular phenotype with the same characteristics (in other words, all the proteins have the same function, but possibly with different levels of activity h). We used this property to define the two following classes:

Simple organisms (*Simples*) are organisms for which all the non-degenerated proteins have the same function (*i.e.*, the same m and w values, both with an $\varepsilon = 0.001$ tolerance), possibly with different activity levels (h). Figure 2.B shows an example of a simple individual. Note that all organisms owning a single protein are necessarily simple but that *Simples* may contain many genes and many proteins (possibly differing in their h values). Hence, *Simples* can have different levels of functional complexity $\mathcal{C}_P$.

Complex organisms (*Complexes*) are organisms owning at least two non-degenerated proteins for which either the triangle mean m or the triangle half-width w values are different (with the same tolerance ε). Figures 2.C and 2.D show an example of a complex individual.

2.4 Measure of robustness and evolvability

To measure robustness and evolvability in Aevol, we used a Monte-Carlo sampling procedure: starting from the final populations, we first retrieved the common ancestor at generation 250,000. Then, we used Aevol to produce 10,000,000 offspring of this ancestor. By measuring the fitness of these offspring and comparing it to their parent's, we were able to measure the local curvature of the fitness landscape and hence to estimate robustness and evolvability of the ancestral clone.

2.4.1 Measure of robustness

Robustness can be defined in several ways. Here we considered *replication robustness*, *i.e.* the ability of an organism to replicate neutrally. Replication robustness must not be confused with *mutational*

robustness (the ability of an organism to conserve its fitness in spite of the mutations it has undergone) as replication robustness also accounts for the fraction of organisms replicating without undergoing any mutation.

From the 10,000,000 offspring, replication robustness can be estimated directly by measuring F_ν the fraction of offspring that retain the fitness of their parent [14].

2.4.2 Measure of evolvability

Evolvability is a complex concept for which many definitions have been proposed in the literature [26]. Here we use the definition inspired by [34]: evolvability — or evolutionary potential — is here quantified as the expectation of gain at the next generation. Hence, provided the sampling is large enough, evolvability can be estimated by the same procedure as robustness. However, obviously, such an evolvability measure is strongly dependent on the distance to the optimum (the closer to the optimum, the less evolvable an individual is likely to be). Hence, contrary to robustness, evolvability cannot be estimated directly from the naive replication of an ancestral clone: since simple organisms are closer to the optimum than complex ones (see results), their respective evolvability measures would not be directly comparable. To avoid this pitfall, we measured evolvability of the ancestor in a modified environment (*i.e.* an environment which target function is still an isosceles triangle but which mean m has been slightly drifted from 0.5 to 0.495). In this new environment, all the organisms are positioned away from the (new) optimum whatever their complexity, and the fitness of the *Complexes* and of the *Simples* become indistinguishable (data not shown). Then, from the 10,000,000 offspring (see above), we recorded the favorable mutants (*i.e.*, offspring whose fitness is higher than their parent's) and computed evolvability as the expectation of fitness gain at the next generation, *i.e.* the sum of the fitness gain of these mutants divided by the number of samples (10,000,000).

2.5 Evolution with no selection

In order to test whether the ZFEL [21] could be a driver of the increase in diversity and complexity in our experiments, we evolved populations without selection. To this aim, we first selected two individuals, one *Simple* and one *Complex*, in the lineages at generation 250,000. These two individuals were chosen as follows: we first extracted the 100 ancestors at generation 250,000 in each of the populations that evolved under a low mutation rate (10^{-6} mut.bp $^{-1}$.gen $^{-1}$). These 100 individuals were then classified into *Simples* and *Complexes*. We computed the median functional complexity ($\mathcal{C}_P$)

of each group and, in each group, selected the individual which $\mathcal{C}_P$ value was closest to this median. We thus selected the most representative individual in each complexity class.

We used these two individuals, to initialize 20 clonal populations (10 for the *Simple* and 10 for the *Complex*). These populations were then evolved for 10,000 generations under a 10^{-6} mutation rate with no selection (*i.e.* each individual has the same probability of replication regardless of its distance to the environmental target). Meanwhile we measured (*i.*) the fraction of *Complexes* in each population, (*ii.*) the diversity of genomic complexity ($\mathcal{C}_G$) and functional complexity ($\mathcal{C}_P$) in each population (estimated by $\mathcal{C}_G$ and $\mathcal{C}_P$ variances) and (*iii.*) the mean genomic and functional complexity in each population.

3 Results

Among the 300 simulations we analyzed (3 mutations rates with 100 repeats each), 229 were classified as *Complexes* (see section 2.3) at generation 250,000. Table 1 shows the distribution of simple and complex organisms for the three mutation rates we analyzed.

Mutation rate (μ)	Number of <i>Simples</i>	Number of <i>Complexes</i>
10^{-4} mut.bp ⁻¹ .gen ⁻¹	32 [24 – 43]	68 [58 – 76]
10^{-5} mut.bp ⁻¹ .gen ⁻¹	25 [18 – 34]	75 [66 – 82]
10^{-6} mut.bp ⁻¹ .gen ⁻¹	14 [9 – 22]	86 [78 – 91]

Table 1: Number of simple and complex lineages at generation 250,000 for the three tested mutation rates. Brackets show the 95% confidence intervals (CI_{95%}) estimated from the number of samples in both classes using Wilson method.

We first verified that the complex organisms (respectively the simple ones) correspond to those accumulating information (resp. not). Figure 3 shows the quantity of information stored on the genomes (Genomic complexity, $\mathcal{C}_G$) and on the proteomes (Functional complexity, $\mathcal{C}_P$) for simple and complex organisms and for all the mutation rates. Note that $\mathcal{C}_G$ and $\mathcal{C}_P$ cannot be quantitatively compared since they account for information content in a binary sequence and in a set of real values respectively.

Figure 3 clearly shows that *Simples* tend to accumulate less information in their proteome. The quantity of information stored on the genome also tends to be smaller for *Simples* although the difference is less pronounced (Figure 3, left). This is not surprising given that our qualitative classification is based on the proteome structure and that Aevol allows degrees of freedom between the information

Figure 3: Distribution of complexity measures for the *Complexes* (top) and *Simples* (bottom) at generation 250,000. Left: Genomic complexity ($\mathcal{C}_G$). Right: Functional complexity ($\mathcal{C}_P$). Colors indicate the mutation rates. Blue: 10^{-4} mut.bp $^{-1}$.gen $^{-1}$; Red: 10^{-5} mut.bp $^{-1}$.gen $^{-1}$; Green: 10^{-6} mut.bp $^{-1}$.gen $^{-1}$

coding in the genome and the information coding in the proteome (see model description in section 2.1). Both measures also show a strong effect of mutation rates: the higher the mutational pressure, the lower $\mathcal{C}_G$ and $\mathcal{C}_P$. This is not a surprise either, since the effect of mutation rate on genome structure has already been described in the literature [14, 11]. Contrary to the trend on the amount of information, this effect is more pronounced on the genome, probably because mutational effects directly affect the genome but only indirectly affect the proteome.

3.1 Simple organisms are fitter than complex ones

Having observed organisms evolving either simple or complex functional structure in the same simple environment, the decisive question is whether or not complexity is driven by selection. Figure 4 shows the fitness of the common ancestor at generation 250,000 (see section 2.2) against $\mathcal{C}_G$ (left) and $\mathcal{C}_P$ (right). It clearly shows that simple organisms have a higher fitness than complex ones. This is confirmed by the fitness distribution among the two qualitative classes: Figure 5 shows that all *Simples* reach a fitness that approaches 1, the best possible fitness in Aevol (mean fitness of *Simples*: 0.99 ± 0.008). By contrast, the fitnesses of *Complexes* range on the whole interval, most *Complexes* having a fitness below 0.5 (mean fitness of *Complexes*: 0.42 ± 0.32)

This result demonstrates that in our simulations, it is not selection that drives the populations

Figure 4: Fitness of the common ancestor at generation 250,000 as a function of (left) genomic complexity $\sim \log(C_G)$ and (right) functional complexity $\sim \log(C_p)$. Triangles and circles indicate lineages classified as *Simple* or *Complex* respectively; Same color code as in Figure 3.

Figure 5: Distribution of fitness values at generation 250,000 for *Complexes* (top) and *Simples* (bottom). Same color code as in Figure 3.

toward functional simplicity or complexity. On the opposite, here, complex functional structures evolve *in spite* of selection.

3.2 Complex organisms are neither more robust nor more evolvable than simple ones

It has been shown that, in some situations, indirect selection (*i.e.* selection for robustness or evolvability) can be strong enough to overcome direct selection for fitness [33]. We thus estimated robustness and evolvability of simple and complex organisms at generation 250,000 (see section 2.4) to check whether these properties could explain the evolution of complex functional structures.

Figure 6 displays the replication robustness (left) and evolvability (right) measures for the simple and complex organisms and for all mutation rates. It clearly shows that simple organisms are more robust than complex ones, whatever the mutation rate. On the opposite, there is no clear trend on evolvability since *Simples* or *Complexes* can be more or less evolvable from each other (or even indistinguishable) depending on the mutation rates.

Figure 6: Estimate of the replication robustness (left) and evolvability (right) of the complex (red) and simple (blue) organisms at generation 250,000 for each tested mutation rate.

The difference of robustness between the *Simples* and the *Complexes* is relatively straightforward to explain. Indeed, complex individuals own a larger genome on which they accumulate more information (Figures 3 and 8). Consequently, they present a larger mutational target and — for a given mutation rate — a larger number of mutational events. Hence, their replication robustness is lower [10, 11, 14].

Our results on evolvability deserve attention as it is often assumed that complex structures are more evolvable than simple ones [29]. However, this common assumption is strongly rooted in modularity [8], a property that has no reason to evolve here. To better understand our results, we distinguished the two components of evolvability: the fraction of positive offspring and the mean fitness gain of the positive offspring (Figure 7). This shows that *Simples* have a significantly lower fraction of favourable

Figure 7: Fraction of positive offspring (left) and fitness gain among positive mutants (right) of the complex (red) and simple (blue) organisms at generation 250,000 for each tested mutation rate. Simple organisms have a lower fraction of positive mutants but these mutants are often closer to the optimum than those issued from complex organisms.

Figure 8: Genome size for the *Complexes* (red) and *Simples* (blue) at generation 250,000 for each tested mutation rate. Genomes of *Complexes* are significantly larger than genomes of *Simples*

offspring than *Complexes* and that the fitness gain of the former is slightly higher than the fitness gain of the latter even though they are already closer to the environmental target (the difference between mutation rates being explained by the difference of fitness between *Simples* having evolved under different mutation rates, see Figure 5). In other words, the *Complexes* have more possibilities to increase their fitness — which is coherent with their lower robustness and larger mutational target

— but these possibilities result a lower fitness gain.

These results show that, although the fitness landscape is the same in all our experiments, *Simples* and *Complexes* lie in very different parts of the landscape. *Simples* lie in high, steep, regions but with a low connectivity while *Complexes* lie in low, flat, highly connected regions. This may seem contradictory with the higher robustness of the *Simples* (as mutational robustness is higher in flat regions of the landscape [33]) but one has to remember that we estimated *replication* robustness; a property that not only depends on the fitness landscape but also on the amount of non-coding sequences [14]. Indeed, in our simulations, mutational robustness of the *Complexes* is approximately twice that of the *Simples* (except for the highest mutation rates where they are not significantly different — data not shown).

To conclude, our measures of robustness and evolvability demonstrate that in our simulations, the choice between functional simplicity and functional complexity is not driven by indirect selection for either robustness or evolvability. On the opposite, here again, complex functional structures evolve in spite of indirect selection.

3.3 In the absence of selection, complexity quickly drops to zero

Previous results claim for a non-selective driving of complexity increase, *e.g.*, by the ZFEL [21]. We assessed the effects of selection by letting organisms evolve in new conditions where selection had been neutralized. Starting from two homogeneous populations (one populated by complex individuals and the other by simple ones), we let them evolve for 10,000 generations, in the absence of selective pressure, and measured the diversity and complexity at both the genomic and the functional levels. This process was repeated ten times for the two initial conditions (see section 2.5).

Figure 9 shows the proportion of *Complexes* in these experiments (top: initial population of *Complexes*; bottom: initial population of *Simples*). It shows that, when a population of complex individuals replicates with mutations but without selection, the proportion of *Complexes* quickly drops to zero. When a population of *Simples* replicates in the same conditions, the proportion of *Complexes* initially grows, up to 20% in the conditions of our experiment, which could seem to support the ZFEL. However, after a few hundred generations, the number of *Complexes* starts to decrease, eventually reaching zero (*i.e.* virtually none of the individual in the population is complex at generation 10,000).

To understand this result, we analyzed the variation of diversity and complexity in the populations, both at the genomic and functional levels. Figures 10 and 11 show the evolution of variance (left) and

Figure 9: Fraction of complex individuals in populations evolving with no selection for a population initially composed of *Complex* clones (top) or *Simple* clones (bottom). Colors indicate the different repetitions.

mean (right) of complexity measures among the populations for the ten repetitions initiated with a *Complex* (resp. *Simple*) individual, at the genomic (top) and functional (bottom) levels. In accordance with the ZFEL prediction, both figures show that the variance of complexity levels initially increases for the two complexity measures (left panels in Figures 10 and 11). This shows that, in the absence of selection, there is an increase of the level of diversity in the population. However, similarly to the proportion of *Complexes* shown on Figure 9, this trend only lasts for a few hundred generations after which the diversity at the genetic level slowly decreases, that of the functional level quickly dropping, eventually reaching zero. Both effects contradict the ZFEL prediction that, in the absence of selection, diversity should increase.

The contradiction is even more clear when looking at the mean levels of complexity in the populations (Figures 10 and 11, right panels). Whatever the initial conditions (*Simples* or *Complexes*) and the complexity measure ($\mathcal{C}_G$ or $\mathcal{C}_P$), in the absence of selection complexity immediately drops, quickly reaching values close to zero.

Taken together, these results show that, in the absence of selection, populations quickly lose complexity, the initial increase of diversity being only due to the different individuals following different paths during this degradation process. Hence, contrary to the prediction of the ZFEL, selection appears as a necessary element to evolve — and actually maintain — horizontal complexity.

Figure 10: Evolution of the variance (left) and mean (right) of complexity measures among the populations for the ten repetitions initiated with a *Complex* individual, at the genomic (top) and functional (bottom) levels.

3.4 Complex organisms evolve greater complexity

So far we have analyzed only one time point: generation 250,000. To address the *dynamics* of the evolution of complexity, we analyzed the fate of simple and complex organisms between generations 10,000 and 250,000. Table 2 shows that most organisms classified as *Simples* or *Complexes* at generation 10,000 conserved this identity thereafter. These values are to be contrasted with the proportion of *Simples* at generation 0 (99%, this high proportion being due to the initialization procedure — see section 2.2), suggesting that most organisms switched from *Simple* to *Complex* between generation 0 and generation 10,000 but that the class they belong to at that time is then part of their identity.

Figure 12 shows the evolution of $\mathcal{C}_G$ (left) and $\mathcal{C}_P$ (right) during the 250,000 generations of the experiment for the simple (blue) and the complex (red) organisms and for the three different mutation rates. It shows that the evolutionary trend is completely different between the two classes: while *Simples* slightly decrease in $\mathcal{C}_G$ and are almost constant in $\mathcal{C}_P$, *Complexes* increase in $\mathcal{C}_P$ while only

Figure 11: Evolution of the variance (left) and mean (right) of complexity measures among the populations for the ten repetitions initiated with a *Simple* individual, at the genomic (top) and functional (bottom) levels.

	$\mu = 10^{-4}$		$\mu = 10^{-5}$		$\mu = 10^{-6}$	
$P_{S \rightarrow S}$	100%	[100% – 87.9%] (28/28)	100%	[100% – 85.7%] (23/23)	92.3%	[98.6% – 66.7%] (12/13)
$P_{C \rightarrow C}$	94.4%	[97.8% – 86.6%] (68/72)	97.4%	[99.3% – 91%] (75/77)	97.7%	[99.4% – 92%] (85/87)

Table 2: Fraction of organisms that conserved their *Simple/Complex* identity between generation 10,000 and generation 250,000 (resp. $P_{S \rightarrow S}$ and $P_{C \rightarrow C}$). Brackets show the $CI_{95\%}$ computed using Wilson method; Values in parentheses give the number of individuals with *Simple* identity – resp. *Complex* – at generations 250,000 and 10,000.

those with a low mutation rate (10^{-6} mut.bp $^{-1}$.gen $^{-1}$) increase in $\mathcal{C}_G$. Indeed, in mean, between generations 10,000 and 250,000, $\Delta\mathcal{C}_G = -43.8 \pm 2.2$ in simple individuals (for all mutation rates) while $\Delta\mathcal{C}_G = +25.3 \pm 1.62$ in complex ones. On the same period, $\Delta\mathcal{C}_P = -0.32 \pm 0.31$ for simple individuals while $\Delta\mathcal{C}_P = +3.58 \pm 0.27$ for complex ones ($CI_{95\%}$ computed from the standard deviation and the number of individuals: $CI_{95\%} = 1.96\sqrt{\sigma^2/N_{I10k}}$).

Figure 12: Evolution of genomic complexity ($\mathcal{C}_G$, left) and functional complexity ($\mathcal{C}_P$, right) between generations 0 and 250,000 for complex (red) and simple (blue) individuals. Plain lines: low mutation rate (10^{-6} mut.bp $^{-1}$.gen $^{-1}$); Dotted lines: medium mutation rate (10^{-5} mut.bp $^{-1}$.gen $^{-1}$); Dashed lines: high mutation rate (10^{-4} mut.bp $^{-1}$.gen $^{-1}$).

Figure 13 shows the evolution of fitness for the *Simples* and the *Complexes* for the three mutation rates. It shows that, whatever the mutation rates, the fitness of *Simples* quickly reaches a very high value, close to the optimum — indirectly confirming the evolvability of simple organisms — and then almost plateaus for the rest of the experiment (mean fitness gain of the *Simples* between generations 10,000 and 250,000: $+0.09 \pm 0.1$). On the opposite, *Complexes* slowly grow in fitness all along the experiment with sustained differences between the different mutation rates (the higher the mutation rate, the higher the fitness): between generation 10,000 and generation 250,000 the mean fitness of the *Complexes* has increased of $\Delta\text{Fitness} = +0.16 \pm 0.05$.

The evolution of $\mathcal{C}_G$ and $\mathcal{C}_P$ for the *Simples* can be easily understood by combining two factors. During the very first generations, their evolution is strongly driven by direct selection and their fitness quickly raise to nearly optimal values (Figure 13). However, after this initial period, direct selection becomes less efficient as there is almost no room for further improvement. The evolution of the *Simples* is then mainly driven by indirect selection for replication robustness. This leads to genome streamlining, specifically in organisms submitted to a high mutation rate (Figure 12, Left, blue dashed line), hence the drop of $\mathcal{C}_G$. However, this mechanism has no clear effect on $\mathcal{C}_P$, because $\mathcal{C}_P$ is already very low and because in the *Simples* there is no selective pressure to increase functional complexity.

The evolution of $\mathcal{C}_G$ and $\mathcal{C}_P$ in the *Complexes* can also be explained by a combination of the effect of direct and indirect selection although the mechanism is different. Since *Complexes* remain far from the

Figure 13: Evolution of Fitness between generations 0 and 250,000 for complex (red) and simple (blue) individuals. Plain lines: low mutation rate (10^{-6} mut.bp $^{-1}$.gen $^{-1}$); Dotted lines: medium mutation rate (10^{-5} mut.bp $^{-1}$.gen $^{-1}$); Dashed lines: high mutation rate (10^{-4} mut.bp $^{-1}$.gen $^{-1}$).

optimum, direct selection is active all along the experiment and $\mathcal{C}_P$ continuously increases, although at a decreasing pace over evolutionary time (Figure 12, Right, Red lines). But this mechanism is constrained by the genomic level that cannot accumulate too much information because of robustness pressures (Figure 12, Left, Red lines; [10, 11, 14]). This robustness pressure imposes a bound on $\mathcal{C}_G$ that strongly depends on the mutation rate. These bounds are clearly visible on Figure 12 (left, red lines), at least for high and medium mutation rates. However, since in Aevol $\mathcal{C}_G$ and $\mathcal{C}_P$ are only softly linked (see model description in section 2.1), these $\mathcal{C}_G$ bounds still allows for the accumulation of functional complexity (Figure 12, right, red lines) and fitness improvement (Figure 13, red lines).

3.5 Effect of harsh robustness constraints on complexity

It is well known that under elevated mutational stress, robust lineages can be selected over fitter ones [33] and that genome compactness is a direct driver of mutational robustness [14]. Here, we have shown that, in our experiments, simple organisms have a higher robustness than complex ones (Figures 4 and 12). Hence, if fitness cannot drive evolution toward complexity reduction, as also shown previously, we hypothesized that robustness might, by imposing a strong complexity limit on the genome.

To test this hypothesis, we submitted the 300 final populations to a harsh mutation rate during 100,000 generations.

Specifically, each population was further evolved with mutation rates μ_{new} 10, 100 and 1,000 times greater than the initial rate (without exceeding the extreme rate of $\mu_{new} = 10^{-3}$). Table 3 shows, for

the different levels of mutation rate increase, the percentage of organisms that, while being complex at generation 250,000, had switched to simple (C→S) at generation 350,000.

	$\mu = 10^{-4}$	$\mu = 10^{-5}$	$\mu = 10^{-6}$
$\mu_{new} = 10^{-3}$	45.9% [58.3% – 34%] (28/61)	64.4% [74.4% – 52.9%] (47/73)	81.2% [88.1% – 71.6%] (69/85)
$\mu_{new} = 10^{-4}$	/	2.7% [9.3% – 0.7%] (2/74)	10.6% [18.9% – 5.7%] (9/85)
$\mu_{new} = 10^{-5}$	/	/	1.2% [6.4% – 0.2%] (1/85)

Table 3: Fraction of Complex→Simple transitions for all pairs of initial (columns) and final (lines) mutation rates. $CI_{95\%}$ computed using Wilson method; Values in parenthesis give the number of Complex→Simple transitions and number of *Complexes* at generation 250,000.

Among the 600 experiments, 463 started with complex organisms. 156 ($33.7 \pm 4.3\%$) of those switched from Complex to Simple (Table 3). Strikingly, while these Complex→Simple organisms experienced a harsh robustness constraint, their fitness strongly increased (mean variation: $+0.69 \pm 0.055$) during the 100,000 generations of the experiment. In contrast, the 307 remaining Complex→Complex organisms experienced a fitness variation of $+0.17 \pm 0.34$. Note that although they retained their complex identity, these organisms experienced a strong complexity decrease in reaction to the mutational pressure ($\mathcal{C}_G$ and $\mathcal{C}_P$ mean variation: -126.1 ± 25.6 and -4.28 ± 0.93 respectively).

Compared to the proportion of Complex→Simple switches between generations 10,000 and 250,000 in the main experiment (8 individuals among 236, see Table 2), the Complex→Simple proportion in the robustness experiments is huge, and even more so when focusing on the extreme mutation rate $\mu_{new} = 10^{-3}$. However, the robustness pressure needs to be very harsh to observe this effect (Table 3). This is probably due to selection for robustness already acting during the first part of the experiment (see above): at generation 250,000 the complex organisms we propagated in the robustness experiment were probably already robust enough to cope with a reasonable increase in the mutational pressure.

4 Discussion

By evolving in a very simple environment populations of digital organisms whose complexity can evolve at the genomic and functional levels independently, we were able to acquire important insights into the evolution of complexity. First, the continuous increase in complexity in such a non-demanding environment is a strong argument in favor of a “complexity ratchet”, *i.e.* an irreversible mechanism

that can add components (or information) to the evolving system but that cannot get rid of existing ones, even though this could be more favorable [7]. Indeed, one of the most astonishing observations is that the complexity ratchet clicks and goes on clicking despite the selective advantage of simple solutions over complex ones and despite their greater robustness. However, by submitting the same organisms to a harsh robustness constraint, we have shown that, contrary to selection for fitness, selection for robustness, when severe, can overcome the ratchet and push complex organisms back toward simplicity. These results may be interpreted as evidence of a non-selective mechanism such as the Zero Force Evolutionary Law [21]. However, we also showed that, in the absence of selection, all forms of complexity quickly vanish in our simulations, excluding the ZFEL as a possible explanation of the ratchet. Given the simplicity of the ZFEL formulation, this deserves a specific discussion. Actually, Brandon and McShea’s argument in favor of the ZFEL are based on a few assumptions, in particular that complexities at the different organization levels are independent from one another and that increase of diversity naturally results in an increase of complexity. But, as shown by our simulations, both assumptions are false, first because complexity at the functional level is encoded at the molecular — genetic — level, hence coupling both levels, second because an increase of diversity at the molecular level may result in a *decrease* of complexity at the functional level. The former is self-evident but the latter deserves explanation: Molecular encoding on the genome is based on consensus signals (promoters, RBS, START codon...) that need to be recognized by molecular “readers” (polymerases, ribosomes...); now, an increase of diversity at the molecular level not only increases diversity of the genes’ sequences (hence of the functional level, as is transitorily observed in our simulations — see Figures 10 and 11, left panels), it also increases diversity of the consensus signals, eventually hindering their ability to be recognized by their readers. A direct consequence is that the increase of diversity at the genomic level actually reduces the number of signals, hence the number of encoded elements, leading to a decrease of complexity at both the genomic and the functional levels (see Figures 10 and 11, right panels).

In our experiments, simple organisms are fitter than complex ones. Previous results with Aevol, showed that selection for robustness favors streamlined genomes [14, 24]; and that the joint effect of duplications and deletions biases mutations toward reduction [11]. Then, if selection, robustness and mutational biases all push in the same direction — simplicity — what is the force that counterbalances them all hence leading to complexity increases? To answer this question, we first have to look back at the variation of fitness along the experiment (Figure 13). It shows that even though *Complexes* stay

far worse than *Simples*, *Complexes* still substantially gain fitness all along the simulation: although complexity increases *in spite* of selection, its increase is nevertheless driven by selection!

This immediately points toward a negative epistasis phenomenon, *i.e.*, the differential effect of a mutation according to the genetic context in which it occurs. Epistasis is largely documented theoretically and experimentally [25] and, interestingly, it has been shown that in natural populations, epistasis correlates with complexity [28]. Here, mutations that would have been beneficial in a given *Simple* individual are deleterious in the genetic context of *Complex* individuals (and reciprocally). Indeed, selection only acts on the basis of the local topology of the fitness landscape, which depends on the genetic background of the individuals. In a complex genetic context, negative epistasis forbids the acquisition of some genes that could be highly favorable in a simple context. Since gene deletion is obviously deleterious, the only available evolutionary path for an already complex organism seems to be a headlong rush toward increasing complexity by acquiring new genes. Hence the ratchet clicks, further widening the fitness valley that separates the current genome from a simple one, soon making it so wide it is very unlikely to be crossed.

The geometric properties of Aevol functional structure provide a good illustration of the ratchet mechanism. In our experiments, the phenotypic target can be fitted by a single triangular kernel/protein. However, as soon as the proteome contains a protein with $m \neq 0.5$ or $w \neq 0.1$, this is no longer possible because the function that *remains* to be fitted (*i.e.* the target minus the protein kernels) becomes multilinear... and the ratchet starts clicking. In other words, each protein added to the proteome increases the complexity of the function that remains to be fitted, forbidding its fitting by a single triangle and triggering further gene recruitment.

Now, if selection cannot overcome the ratchet, how can an increase in mutational pressure? It is known that severe robustness constraints can overcome selection by imposing an upper limit to the amount of information an organism can transmit to its offspring at the genetic [10] and at the genomic [14, 11] levels. In our experiments, raising the mutation rate strongly decreases the storage capacity of the genome, hence forcing gene elimination despite the fitness loss. This can lower epistatic constraints enough to allow the transition from complexity to simplicity.

Table 1 shows that the ratchet does not systematically start clicking: in nearly one quarter of our simulations, evolution leads to simple solutions. Moreover, we saw that the path toward simplicity or complexity is taken very early in the simulations (often before generation 1,000, data not shown) which indirectly confirms that the ratchet is engaged when the organisms recruit their very first genes. But

how is this initial direction determined? Starting with a single gene (see section 2.2), the organisms can evolve in two ways: (1) optimizing this gene by mutation, (2) recruiting new genes, primarily through a duplication-divergence mechanism. Depending on this contingent alternative, akin to a “frozen accident” [9], evolution is more or less likely to lead to either *Simple* or *Complex* identity. However, selection can also play its role in the identity switch: since the route to simplicity leads to higher fitnesses, clonal interference is likely to favor simplicity. Hence, if our explanation is correct, the fraction of *Simples* should increase in very large populations (clonal interference being more frequent in large populations).

The two alternative evolutionary pathways described above also suggest that the negative epistatic interactions that lead to the accumulation of complexity could be due to rearrangement events (typically segmental duplications). We tested this hypothesis by evolving 100 populations in conditions where there is no rearrangement and where the mutation rate (for switches and InDels) is such that the total number of events is equivalent to the medium mutation rate in the main experiment ($\mu = 10^{-5}$ mut.bp $^{-1}$.gen $^{-1}$). We observed that, among these 100 populations, 98 evolved simple functional structures (to be compared with the 25 that evolved simple functional structures in the initial experiment — see Table 1). This confirms the strong role played by chromosomal rearrangements in this process. This also explains why the mechanism we identified here had not been observed previously. Indeed, to the best of our knowledge, Aevol is the sole model that is able to finely account for the rearrangement mechanisms. Hence, our results also strongly call for a better accounting of these overlooked events in artificial life models.

Finally, if contingency can explain the initiation of the ratchet and epistasis its mechanisms, what about its long term behavior? Will the ratchet click forever, thus reaching very high complexities? In our simulations the final complexity seems to be bound despite a great room for improvement in most of the complex organisms (Figures 4 and 12). Indeed, three effects can impose a bound to complexity: (1) As complexity grows, the advantage provided by new genes may become too small for selection to allow for their fixation. Indeed, it has been proposed that genome complexity could be mainly driven by population genetics effects [18]. However this is unlikely to explain the apparent bound we observe since *Complexes* can still improve greatly (Figure 5). (2) Proteome complexity needs to be encoded in the genome but there is an upper bound to the amount of information a genome (hence a proteome) can carry with given mutation [10] and rearrangement [14, 11] rates. (3) The waiting time to the next innovation increases as the organism becomes more complex. This is directly linked to the

“cost of complexity” that slows adaptation down as the number of selected traits increases [23]. In our simulation, *Simples* fit the target globally — as a single trait — while *Complexes* virtually split the target in parts which they fit more or less independently from one another. Hence *Complexes* are likely to suffer from the cost of complexity: as complexity increases evolution slows down in such a way that it would require virtually-infinite waiting time to approach the two above-mentioned bounds.

When experimenting with models, a tricky question is always to tell evolutionary trends apart from model artifacts. Here, we used Aevol, a model that has already proven its consistency, but that nevertheless has its limits. Among them, three at least are likely to interfere with our results. First, as in most ALife models, we deal with very small populations compared to natural populations. As discussed previously, larger population size may change the initial direction toward simplicity or complexity or the upper complexity bounds. However, since selection cannot invert the ratchet we hypothesize that our general conclusions qualitatively hold whatever the size of the population. Second, the properties of our artificial chemistry may differ from real biochemistry. In particular, dosage effects are stronger in Aevol than they are in Nature. However, this property is likely to limit the complexity increase since gene duplications are more deleterious in the model than in Nature. Then, this should not alter our main conclusions. Last but not least, although Aevol is a multi-scale model, it lacks some scales that are likely to play a crucial role in the evolution of complexity. In particular it lacks a complex ecosystem and a gene network. Hence, we cannot observe here the effect of niche construction that could act as an important player in the evolution of complexity [27].

On the gene network side, our results match very well those we obtained when using the RAevol version of the model to evolve genetic networks in constant vs. variable environments [6, 16, 32]. Indeed, in these experiments the complexity of the network appeared to be driven by the mutation rate and highly complex networks evolved even in constant environments. This opens the interesting perspective of replicating the present experiments in RAevol.

Our work opens many other perspectives. Specifically, we would like to analyze the evolutionary dynamic of our populations at a finer grain. In particular, analyzing the effect of every single mutation on complexity, fitness, evolvability and robustness depending on the mutation type (point mutations vs. rearrangements) would allow for a better characterization of the epistatic interactions in the model. Finally, the most engaging perspective would be to generalize the mechanisms observed here to other kinds of systems. Indeed, an open question is whether this complexity ratchet could contribute to Open-Ended Evolution [3], hence opening the door for non-selectively-driven Open-Endedness. A

difficult question here is whether epistasis (and negative epistasis) has an equivalent in other Open-Ended systems such as economy or innovation.

In conclusion, we would like to stress that our results, gathered on a null model, do not imply that there is no such thing as selection for complexity. But importantly, they show that selection for complexity is not mandatory for complexity to evolve. Hence, complex biological structures could flourish in conditions where complexity is not needed. Reciprocally, the global function of these complex structures could very well be simple. We think this result is greatly significant for both evolutionary biology and systems biology.
