Abstract. Organic Electron Donors (OEDs) are increasingly used as efficient reducing agents in various radical reactions. However, their sensitivity to air restraints their practical use and the development of further industrial applications. To meet the community's needs, this paper reports the preparation of air- and moisture-stable carboxylate precursors that can be conveniently activated into the corresponding organic reducer. The new strategy consists in the water-assisted decarboxylation of the adduct at room temperature, providing a straightforward protocol for the single-electron transfer reduction of aryl halides and sulfonamide. The resulting aryl radicals are engaged in the first examples of OED-promoted intermolecular addition reactions. A thorough mechanistic study supports the *in-situ* formation of the organic reducer.

Introduction

Reduction reactions promoted by electron transfer are now recognized as a powerful group-tolerant strategy for new elaborate reactions and rapid increase of molecular complexity.¹ Long limited to toxic and highly aggressive metal-based reducing agents, reduction reactions are enjoying renewed interest since the development of metal² or organic³ photocatalysts. Although used in stoichiometric amounts,⁴ readily-prepared enamine-based Organic Electron Donors (OEDs)⁵ are also attracting attention as a serious alternative as shown by the growing number of useful applications (initiators for coupling reactions or polymerizations, redox switches and flow batteries, greenhouse gas reduction).⁶ They spontaneously promote single- (SET) or double electron-transfers (DET) to substrates that are thermodynamically too uphill for current SET-photoredox catalysts. At ground state, they generate radical or anionic intermediates from substrates with redox potential $E_{1/2} < -1.0$ V.⁷ UV-photoexcitation (365 nm) of OEDs further enhances their reducing power to substrates with $E_{1/2}$ up to -3.5 V.⁸ Depending on their structures, the enamines are stable and can be stored and manipulated under inert atmosphere.^{5,9} In other cases, the dimeric form is elusive and decomposes after a few minutes or hours into the corresponding *N*-heterocyclic carbene (NHC) (Scheme 1).^{9a,10} In addition to these short half-life issues, OEDs like any other strong reducing agents, are highly sensitive to oxygen.¹¹

To overcome these constraints, processes consisting of the activation of air-stable precursors with strong bases^{10,12} or under high working temperatures¹³ have been used to *in situ* generate the reducer. However, strong bases present limited group tolerance and thermal activation (150°C) impedes the use of volatile substrates or solvents. To significantly improve the practicality of OEDs, there is a need for air-stable precursors allowing the convenient *in situ* generation of enamine reducers under mild conditions.

Scheme 1. OED formation through air-stable precursors.

This manuscript illustrates the synthesis and the activation of carboxylate and sulfinate iminium adducts into the corresponding organic reducer. The new strategy consists in the water-assisted decarboxylation (or desulfination) of the adduct at room temperature (Scheme 1). A thorough mechanistic study supports the *in-situ* formation of the enamine-type reducer. Their scope will also be discussed, notably for OED-promoted intermolecular radical addition reactions.

Results and discussion

Our study began by comparing the physico-chemical and activation parameters of various carboxylate and sulfinate adducts. Adapted from reported procedures,^{13,14,15} the adducts were prepared in a two-step procedure involving first

deprotonation of the iminium salt, followed by trapping of the generated species with carbon dioxide or sulfur dioxide atmosphere (Scheme 2). All the precursors were obtained in moderate to good yields (51-98%).

Scheme 2. Synthesis of carboxylate and sulfinate adducts.

While expecting easier cleavage of the SO₂ moiety than the CO₂,¹⁶ thermogravimetric analysis (TGA) at the solid states of these adducts surprisingly indicated that the sulfinate adducts would decompose at higher temperatures than their carboxylate counterparts (**IMe-nBu-SO₂**, 190°C vs. **IMe-nBu-CO₂**, 141°C) (Table 1). However, this physical feature directly contrasted with their instability in air (leading to the formation of hydrogen sulfite salt **IMe-R'.HHSO₃**) and with their higher reactivity in solution under thermal activation (See supporting information (S.I.), Scheme S1 and Table S2).¹⁷

In **NHC-CO₂** series, the presence of bulkier *N*-groups around the carboxylate moiety facilitates the decarboxylation (Table 1, **IMe-CO₂** 140°C vs. **tBu-CO₂** 63°C).^{18,19c} At 150°C, these carboxylate adducts can be decarboxylated to generate an organic reducing species.¹³ Nevertheless, the steric hindrance induced by the *tert*-butyl groups may also impede the efficient formation of the active dimeric OED-form. To balance ease of decarboxylation and dimerization, we prepared **IMe-nBu-CO₂** bearing a longer *N*-butyl chain. However, the decarboxylation temperature of **IMe-nBu-CO₂** was not affected by this slight increase in hindrance, displaying a similar value (141°C) to that of **IMe-CO₂**. Encouragingly, the 1,3-dimethylbenzimidazolium adduct **BzIME-CO₂** showed a low decarboxylation temperature (52°C) and a relative stability of the generated species until its decomposition at 119°C. Despite a first decarboxylation at low temperature (50°C), the loss of the second molecule of CO₂ of the *N,N'*-bridged bis-benzimidazolium carboxylate adduct **Bis-BzIME-CO₂** was not clearly observed before its decomposition at 219°C (S.I., Figure S2).

The lower IR frequency of the carbonyl asymmetric stretching (1632 cm⁻¹) of **BzIME-CO₂** was also in line with the

low frequencies usually observed for adducts more prone to decarboxylation, such as **tBu-CO₂** (1609 cm⁻¹) (Table 1).^{13,18} More thermally stable imidazolium adducts **IMe-CO₂** and **IMe-nBu-CO₂** displayed higher values (1645 and 1657 cm⁻¹, respectively). UV-Vis spectroscopy indicated similar maximum absorption wavelengths (269-277 nm) for all imidazolium and benzimidazolium adducts (Table 1).

Table 1. Physical features of **NHC-CO₂** and **NHC-SO₂**.

We then evaluated the stability of our carboxylate and sulfinate adducts towards water. Indeed, Louie and Falvey showed that the decarboxylation can be facilitated by the presence of water in an organic solvent.^{18,19} While stable in pure water or stored at air, *N*-alkyl **NHC-CO₂** adducts were rapidly decarboxylated when dissolved in a water/organic solvent mixture, yielding the corresponding carbonate salt **NHC.HHCO₃** upon fast protonation of the carbene intermediate (Scheme 3).^{18,19} Fast decarboxylation in a 5% H₂O/dioxane mixture and formation of corresponding carbonate salts were indeed observed by ¹H NMR for our imidazolium and benzimidazolium **NHC-CO₂** series. Sulfinate adducts **NHC-SO₂** also quickly decomposed, since exposure to air moisture was enough to induce the SO₂ cleavage, leading to the corresponding hydrogen sulfite salts (S.I., Scheme S1). Like with *N*-aryl **NHC-CO₂**,¹⁸ water was only hydrogen-bonded to the CO₂ moiety of the aminopyridinium carboxylate adduct **DMAP-Me-CO₂**, and did not trigger its decarboxylation (Scheme 3).¹³

Scheme 3. Water activation of carboxylate adducts.

The same decarboxylation strategy was then performed in the presence of the substrate to reduce (1-iodo-2-(3-phenoxypropyl)benzene) **1a**) (Table 2). 4 equivalents of precursors were used to *in situ* generate 2 equivalents of the dimeric OED form. While activation of **IMe-CO₂** required a high

temperature of 150°C under previous strategy (Entries 1-2),¹³ addition of 5% of degassed water (35 equiv.) led to its decarboxylation at room temperature and to the partial reduction of **1a** (60%) under UV-irradiations (Entry 5).²⁰

As predicted above, the introduction of a longer *N*-alkyl chain did not ease the activation of the precursor. Compared to **IMe-CO₂**, water activation of **IMe-ⁿBu-CO₂** led to the same reduction of **1a** (Entry 6, 60%). On the other hand, the higher steric hindrance of **i^tBu-CO₂** facilitated the decarboxylation, providing a slight higher reduction rate (Entry 7, 69%).²¹ As expected from the weakness of the longer C-SO₂ bond, the sulfinate adducts **IMe-Et-SO₂** and **IMe-ⁿBu-SO₂** performed better than their carboxylate counterparts under thermal activation (S.I., Table S2, entries 10-11, 99 and 69% respectively at 120°C *versus* 6% for **IMe-CO₂**) (underlying the easier loss of the SO₂ moiety). Nevertheless, the low reducing reactivity observed upon water activation (Table 2, Entries 8-9, 16 and 14%) and their poor stability at air storage clearly disqualified them as convenient OED-precursors.

As anticipated from our stability study, hydrogen-bonding of water to the aminopyridinium carboxylate **DMAP-Me-CO₂** was not sufficient to induce an efficient decarboxylation, leading only to traces of reduction product (Entry 10, 6%). In line with the TGA and IR conclusions, the benzimidazolium precursor **BzIMe-CO₂** offered the best reactivity, with 80% reduction at room temperature (Entry 11). The *N,N'*-trimethylene-bridged derivative **Bis-BzIMe-CO₂** might have induced faster formation of the dimeric reducing agent, *N,N'*-bridged dibenzimidazolin-2-ylidene **DiBzIMe**. However, its lower reactivity (Entry 12, 27%) was consistent with the sluggish second decarboxylation process predicted by TGA.

Evaluation of the influence of water showed that a decrease or an increase over the range of 1.5–10% H₂O slightly decreased the reduction rate (Entries 11, 14-16). As expected, absence of water was deleterious for the formation of the active reducing species (Entry 13, 61%). These fluctuations highlight the impact of the first activation step on the reaction outcome. Efficient decarboxylation of the precursor required 5% concentration of water in DMF. This 5% H₂O concentration also provided fast decomposition rates of **IMe-CO₂** in Falvey's study.¹⁹ Likewise, a trend towards faster decomposition was observed with decreasing solvent polarity (Entries 11, 17-19). Non-polar solvents decrease the dipole moment, destabilizing the zwitterionic adduct and easing the release of CO₂.¹⁹ The best reduction reactivities were observed with less polar THF and 1,4-dioxane (Entries 18-19, 90 and 99%) compared to polar DMF and CH₃CN (Entries 11 and 17, 80 and 68%). This decrease in solvent polarity did not seem to be detrimental to the second step of electron-transfer. In these optimized 5% H₂O/1,4-dioxane conditions, the precursor **BzIMe-CO₂** was thus the best candidate, giving a high yield of the reduced product **2a** (Entry 19, 90%). The OED-precursor **BzIMe-CO₂** was still active after several months of storage in air.

Several experiments were then performed to elucidate the mechanism behind this reduction process and confirm the formation of dimeric OEDs upon water activation of the

carboxylate adduct (Table 3). First, evidence supporting an electron transfer mechanism was obtained through the addition of commonly used inhibitors. The reduction of **1a** was drastically diminished in the presence of inhibitors such as the radical trap TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy) (40%), oxygen (44%) or the competitive electron acceptor *p*-DNB (*para*-dinitrobenzene) (0%) (Entries 2-4).

^a Degassed water. ^b Conversion determined by ¹H NMR analysis. ^c Data excerpted from Ref. 13. ^d Without hv. ^e 2 equiv. ^f Yield.

To gain insights into the active reducing species at work in this process, we first compared the reduction of **1a**, directly using the active reducer di-1,3-dimethylbenzimidazolin-2-ylidene **DiBzIMe** (*E*_{1/2}(DMF) = - 0.88 V vs. SCE) or the precursor form **BzIMe-CO₂**. With both electron sources, reduction of iodoarene **1a** required UV-irradiations to proceed (Table 3, Entries 1,7 vs. 5,8).²² This is not surprising, as dibenzimidazolinylidene-type OEDs, such as **DiBzIMe**, are SET-reducers (*E*_{1/2} ≈ - 0.8 V vs. SCE) only able to reduce aryl iodide under high temperatures (>100°C) or UV-photoexcitation (λ = 365 nm).^{5,12a}

Although the contribution of water was unquestionable (Table 3, Entry 1 vs. 6), note that UV-irradiations alone could also participate to the decarboxylation step of **NHC-CO₂** precursors (Table 2, Entry 3 and Table 3, Entry 6). Compared to thermal activation, **1a** was reduced at drastically lower temperatures (90°C with **IMe-CO₂**, 30°C with **BzIMe-CO₂**) albeit at lower conversion rates (76 and 64 %, respectively). Our UV-LED light source emits at a wavelength (λ = 365 ± 5 nm) out of the range of wavelengths absorbed by **NHC-CO₂** (224-330 nm, Table 1). Hence, rather than a photoexcitation of the

carboxylate adducts, we attribute this activation of **IMe-CO₂** and **BzIMe-CO₂** to localized temperature rises induced by UV radiations, assisting the elimination of CO₂ and drastically decreasing the need for external heating. The slight increase of media temperature (+5°C at r.t) under UV-irradiations plus the polarity effect of the dioxane, that destabilizes the zwitterionic adduct, might be sufficient to slowly activate the decarboxylation of **BzIMe-CO₂** (T-CO₂ = 52°C by TGA of the solid state, Table 1).

^a Observed by ¹H NMR. *hν* (1 LED, 365 nm, 5 cm).

We also compared the benzimidazolium derivatives present at the end of reduction reactions (Table 4). According to the experiment, three derivatives could be retrieved: the 1,3-dimethylbenzimidazolium salt **BzIMe.HX (3)**, the 1,3-dimethylbenzimidazolin-2-one **BzIMeO (4)** or the tetramethylbibenzimidazolium salt **DiBzIMe²⁺ (5)**. **BzIMeO** arises from the autoxidation of **DiBzIMe** (Entry 4)²³ and **DiBzIMe²⁺** is the characteristic DET-oxidized form of **DiBzIMe** (Entry 5).^{5,24} The benzimidazolium salt **BzIMe.HX** can arise either from the

protonation of 1,3-dimethylbenzimidazolin-2-ylidene carbene **BzIMe** or from the reaction of **DiBzIMe** with electrophiles, **DiBzIMe²⁺** with H⁺, or **DiBzIMe²⁺ (5)** with bases.²⁴ Interestingly, reduction of **1a** using either **BzIMe-CO₂** or **DiBzIMe** led in both cases to the recovery of largely **3** and traces of **4**, but no trace of **5** (Entries 2-3). The absence of **DiBzIMe²⁺** was explained by the instability of the radical cation **DiBzIMe^{•+}** under UV-irradiations (S.I., Scheme S3-S4). As matter of fact, ET-oxidation of **DiBzIMe** with C₂Cl₆ as strong oxidant gave a 1/1 mixture of **3** and **5** under UV-irradiations (Entry 6 vs. 5). Hydrogen atom transfer (HAT) to radical cation **DiBzIMe^{•+}** would lead to the unstable adduct **DiBzIMeH⁺**, which dissociates into salt **3** and carbene **BzIMe** (Scheme 5).²⁴ Such unstable **DiBzIMeH⁺** can also be obtained upon reaction of **DiBzIMe²⁺** with **DiBzIMe**.^{25,26}

It could be argue that under UV-irradiations the carbene 1,3-dimethylbenzimidazolin-2-ylidene (**BzIMe**) itself could promote the single electron-transfer reduction of iodoarene **1a**. Benzimidazolium salt **3** would also be the resulting oxidized species (Scheme 4). *N*-heterocyclic carbenes are theoretically able to donate an electron, even though they have very low reducing powers (e.g. for the 1,3-bis(2,4,6-trimethylphenyl)imidazolin-2-ylidene (**IMes**): E_{1/2}(DMF) = - 0.20 V vs. SCE).²⁷ In the case of the **i^tBu-CO₂** precursor, the **i^tBu** carbene could indeed be the electron donor species considering its sterically disfavoured dimerization (Table 2, Entry 7).²¹ Nonetheless, with **BzIMe-CO₂** as precursor, the half-life of the **BzIMe** carbene ought to be very short. The inclination of *N,N'*-dimethylbenzimidazolium salts to rapidly and tightly dimerize upon deprotonation is well reported.²⁸ Lemal briefly observed trace of **BzIMe** through dissociation of **DiBzIMe** at high temperature (140°C), but the signal rapidly disappeared upon cooling.^{28a} This demonstrates the high stability of **DiBzIMe** and the reversibility of the process. In our case, both thermal decarboxylation of **BzIMeCO₂** (S.I., Scheme S5) and deprotonation of **BzIMe.HI** salt (S.I., Scheme S2) allowed fast formation of the dimer species **DiBzIMe**. Monitoring of the decarboxylation of **BzIMe-CO₂** by ¹H and ¹³C NMR at 70°C in C₆D₆ detected the formation of **DiBzIMe** but no trace of carbene **BzIMe**, even after several days of heating (Scheme 5). Moreover, when the reaction was performed with one equivalent of carboxylate **BzIMe-CO₂**, only 63% reduction was observed, consistent with *in situ* generation of 0.5 equivalent of the reducing dimeric form **DiBzIMe** (the remaining 13% accounted for direct homolytic cleavage of **1a** under UV-irradiations, Table 3, Entry 11).

Scheme 4. Candidate pathways using benzimidazolium carboxylate for the ET-reduction of iodoarenes.

The contribution of the carboxylate form as active donor species was also considered. Direct photoexcited SET from **BzIme-CO₂** to **1a** would generate the corresponding aryl radical and the carboxyl radical species **BzIme-CO₂[•]** (Scheme 4). **BzIme-CO₂[•]** would decompose into salt **3** upon decarboxylation and HAT. In fact, carboxylate derivatives are known as reducers able to promote photoinduced electron transfer to very strong acceptors (Ir* and Ru* complexes or organic dyes).²⁹ An electron-rich amino group near the carboxylate moiety is necessary to assist the electron transfer and the decarboxylation process. However, in our case, the electron-poor iminium moiety of **BzIme-CO₂** should disfavor any electron transfer from the carboxylate group to a poor acceptor like an iodoarene. The lack of reactivity of the aminopyridinium carboxylate **DMAP-Me-CO₂** (Table 3, Entry 10), presenting no sign of decarboxylation under these conditions, also makes it reasonable to conclude that the carboxylate form is not the active reducing species.

All these arguments suggest that the *in situ* generation of **DiBzIme** proceeds according to the following mechanism (Scheme 5): Water-assisted decarboxylation of **BzIme-CO₂** leads to the formation of the 1,3-dimethylbenzimidazolin-2-ylidene **BzIme**, which is protonated into benzimidazolium salt

3. Falvey showed that these two steps were stepwise and not concerted.¹⁹ A second molecule of **BzIme** is added to salt **3** to form the cation intermediate **DiBzImeH⁺**. Rapid deprotonation of **DiBzImeH⁺** with **BzIme** leads to the formation of the active reducer **DiBzIme** and regenerates **BzIme.HHCO₃** (**3**). This acid-catalysed dimerization of **BzIme**, where **3** is the acid, allows a complete shift of the Wanzlick enamine/carbene equilibrium toward the dimer form **DiBzIme**.³⁰ Small amounts of **DiBzIme** could also come from the thermal decarboxylation of **BzIme-CO₂** under the UV-irradiation conditions.²⁰ Photo-excited **DiBzIme** then transfers a single electron to the iodoarene **ArI**, leading to the corresponding aryl radical **Ar[•]** and the radical cation **DiBzImeH^{•+}**. The aryl radical **Ar[•]** abstracts a hydrogen from the 1,4-dioxane to generate the final reduced compound. Disproportionation or HAT of the radical cation leads to the formation of the unstable cation **DiBzImeH⁺** which decomposes into salt **3** and carbene **BzIme**. The generated carbene can in turn form **3** after protonation.

To further investigate the scope of this water-activated OED-precursor, we examined the reduction of various aryl substrates, and their subsequent intramolecular and intermolecular radical addition on alkenes. Water activation of **BzIme-CO₂** and UV-excitation of the as-formed **DiBzIme** promoted the SET-reduction of various iodide and sulfonamide arenes **1a-j** in moderate to excellent yields (Scheme 6). Exclusive formation of reduced products **2b** and **2c** (i.e. with no trace of the cyclised derivatives obtained by DET, S.I., Table S3) was in line with the SET capacities of **DiBzIme**.^{12a} The reducing system was tolerant to different functional groups including ester (**2b**, **2c** and **2d**), ketone (**2e**) or cyano groups (**2f**), characteristic of the chemo-selectivity of OEDs. Bromoarenes with more negative reduction potentials were also partially reduced (**2a**, Y = Br and **2f**). These highly challenging reduction reactions prove that the potency of **DiBzIme** was maintained after *in situ* generation from **BzIme-CO₂**.

The aryl radicals obtained through reduction of the Csp^2 -I bond were further engaged in intramolecular additions on alkenes *via* a 5-*exo-trig* cyclisation reaction, leading to the 2,3-dihydrobenzofuran products **7** and **10** (Scheme 7). Formation of **8** arose from a recombination between the cyclized radical and traces of iodide radical generated upon UV-induced homolytic cleavage of the C-I bonds in **6** (Table 3, Entry 11, blank reaction). The cyclized radical obtained from **9** could either abstract a hydrogen to give **10** or disproportionate to give **11**.³¹ Starting materials **6** and **9** accounted for the mass balance.

Scheme 7. Intramolecular aryl radical additions on alkenes.

Our strategy of *in situ* generation of a powerful OED from an air-stable precursor also affords the first example of OED-promoted intermolecular additions of aryl radicals to alkenes (Scheme 8). The aryl radical resulting from the complete reduction of **12** was added to the external position of the diphenylethylene **13** to obtain the 1,2-diphenylethylbenzene derivative **14** in 36% yield. The moderate yield probably accounted from the competitive formation of volatile chlorobenzene (**15**) upon HAT to the aryl radical. The α -substituted pyrrole derivative **17** was obtained in excellent yield through intermolecular addition of the aryl radical of **12** on the pyrrole **16**. Rearomatization of the pyrrole moiety of **17** probably occurs through radical coupling of the alkyl radical with the radical cation DiBzIme^{*+} , followed by elimination of the resulting benzimidazolium leaving group.³²

Scheme 8. Intermolecular aryl radical additions on alkenes.

Conclusions

In conclusion, we demonstrated that water can enhance the decarboxylation of air-stable imidazolium and

benzimidazolium carboxylate adducts and thus allow the *in situ* generation of strong organic electron donors at room temperature. Photo-excited di-1,3-dimethylbenzimidazolin-2-ylidene **DiBzIme** then promotes the efficient single-electron transfer reduction of sulfonamide and aryl halides. The resulting aryl radicals are then engaged in intramolecular and intermolecular additions to alkenes. A thorough mechanistic study supports the activation pathway and the *in-situ* formation of the organic electron donor. The multiple strategies that we developed for the activation of *N*-heterocyclic carboxylate adducts (thermal-, water- or UV-activation) ensure their practicality and should foster their use as air-stable precursors of powerful organic electron donors in radical chemistry.

Acknowledgements

The Agence Nationale de la Recherche is gratefully acknowledged for the JCJC ANR grant “iPOD” (17-CE07-000101). Aix Marseille Université (AMU) and the Centre National de la Recherche Scientifique (CNRS) are also acknowledged for financial support. GT thanks the Ministère de l'Enseignement supérieur et de la Recherche for his Ph.D. grant. YZ thanks the China Scholarship Council for his Ph.D. grant. We thank Dr. Vincent Remusat for NMR analyses and the Spectropole (Fédération des Sciences Chimiques de Marseille) for spectroscopic analyses.

- 17 Similarly, we had already demonstrated that the decarboxylation temperature of the solid **DMAP–Me–CO₂** (181°C) was overestimated compared to the temperature of activation observed in solution (120°C).¹³ This was attributed to the well-organized arrangement of the solid **DMAP–Me–CO₂** favouring strong hydrogen-bond interactions.

- 20 All reactions were carried out in the presence of two cooling fans to avoid a rise of temperature due to UV-irradiations. The temperature media did not exceed 30°C.
- 21 Considering the strong constraint of the ^tBu groups and the inclination of imidazolium series to form carbenes rather than enamine dimers in the Wanzlick equilibrium,¹⁰ we cannot totally exclude the sole formation of ^tBu carbene in this case. Under UV-irradiations, ^tBu could be the active electron donor, transferring one electron to the substrate **1a**.
- 22 Water was not necessary for the reduction of **1a** using two equivalents of **DiBzIme** under UV-irradiations. But water was left to keep the reaction conditions as close as possible to the ones used with **BzIme–CO₂**.
- 23 Note that no reduction was observed using **BzImeO** as reducer source (Table 3, Entry 9).
