L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

The inner heterogeneity of ZSM-5 zeolite crystals

Yanfeng Shen,^a Zhengxing Qin,^{*a} Shunsuke Asahina,^b Natsuko Asano,^b Guanqun Zhang,^c Shuya Qian,^a Yanhang Ma,^c Zifeng Yan,^a Xinmei Liu,^a and Svetlana Mintova^{*a,d}

Abstract: The inner architecture of zeolite crystals beneath the zeolite surface is the missing part in understanding the crystallization of zeolites and in their thoughtful post-synthesis engineering. In this work, both the defect-zoning and Al-zoning in pseudo-single ZSM-5 crystals were revealed using unbiased NH₄F etching of as-synthesized and calcined samples. The formation of defect-zoning leading to multiple core-shell structure was described with a three-stage process involving (i) nucleation resulting in the innermost core formation, (ii) fast aggregate growth leading to defect-rich zones, and (iii) layer-by-layer growth shaping the final morphology of the zeolite crystals. A clear correlation between Al zoning and the spatial distribution of C and Na was established. This distinct inner heterogeneity in the ZSM-5 crystals reveals the particularities of the crystal growth process of this very important zeolite, and this knowledge can be translated into novel framework structures with targeted properties.

1. Introduction

Zeolites are widely used as catalysts or adsorbents in many commercial processes. In the future, their impact is expected to be broadened, especially in the processing of fossil fuels and a variety of new feedstocks.^[1-3] The tailored design of efficient zeolite materials for these diversified applications depends greatly on the deep understanding of the arrangement details of the internal components of zeolite crystals that determine their properties and potential applications.

The complex crystal growth process of zeolites is represented as a synergy between solution mediated and solid-phase transformation.^[4-7] Extensive microscopic and spectroscopic study of the intermediate and final products led to a substantial understanding of the zeolite crystal growth process.^[8-14] For example, atomic force microscopy and scanning microscopy provided dynamic surface morphology information at nanoscale level and evidence for layer-by-layer growth and crystallization of MFI, LTA, CHA zeolites via oriented nano-particle attachment.^[14-17] The spatial heterogeneities in crystallographic orientation and chemical composition of MFI and FER zeolites were revealed as well.^[18-22] The structural investigation using X-ray diffraction gives key insights into the size of the coherent domains, the unit cell volume, the modification of space groups, and the presence of lattice imperfections and strain of MFI and FAU zeolites.^[23-25] Besides, time-resolved multinuclear ¹³C, ²³Na, ²⁷Al, and ²⁹Si MAS NMR spectroscopy have also been applied for monitoring the mechanistic pathways of BEA and FAU zeolites.^[6,26] By using high resolution transmission electron microscopy, the entire sequence of crystallization events in LTA-type zeolite has been monitored.^[27] We recently revealed the twinning and the hidden “mosaic” structure of MFI and MOR zeolite crystals.^[7]

Despite these findings the comprehensive understanding of zeolite crystallization from atomistic arrangements to ultimate (maturated) zeolite crystals is still under discussion. The main methods applied up to now either average information over the entire volume of the zeolite sample or partially visualize the outermost surface of zeolite crystals. Understanding the inner architecture beneath zeolite surface is of crucial importance for the tailored-design of zeolites. The questions that need to be answered are as follows: (i) how the 2D self-assembly of low-weight molecules and 3D

attachment of oriented particles compete and cooperate in a dynamic inhomogeneous system leading to crystal growth; (ii) what is the consequence of such concerted actions on the structure of zeolite crystals especially in the presence of structure building units of different properties (chemical composition, particle size, solubility) coexisting with organic and inorganic structure-directing agents having different stereospecificity and charging properties; (iii) to which extent the reaction system can be considered as inhomogeneous; and (iv) how the heterogeneity of the precursor inherited into the final zeolite product.

Herein, we reveal the inner structural details and the spatial elements distribution of MFI type zeolite crystals, and explore the underlying mechanisms leading to the inhomogeneous structure formation. In contrast to *in situ* studies of crystals growth process of zeolites reported up to now, we based our study on matured zeolite crystals subjected to “top-down” post-synthesis chemical treatment.^[7] Detailed analysis of the internal architecture of these zeolite crystals provides unique insights into zeolite crystallization process and reveals the ubiquitous presence of defect-zoning and Al-zoning in zeolite crystals.

2. Experimental Section

2.1 Materials preparation

2.1.1 Synthesis of ZSM-5 crystals

For the zeolite synthesis, all chemicals were purchased from Sinopharm Chemical Reagent Corporation and used directly without further purification. 2.5 g sodium hydroxide (NaOH, 96 wt.%) and 20.3 g tetrapropylammonium hydroxide (TPAOH, 25 wt.%) were first dissolved in 450 g deionized water in a polypropylene bottle at room temperature under magnetic stirring. Then 3.75 g aluminum nitrate ($\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$, 99 wt.%) was added into the alkaline solution, followed by the adding of 52 g tetraethyl orthosilicate (TEOS, 28.4% calculated as SiO_2). The mixture was kept at room temperature under magnetic stirring overnight to ensure the hydrolysis of TEOS. The final molar ratio of the synthesis gel was as followed: $0.125 \text{ Na}_2\text{O} : 0.05 (\text{TPA})_2\text{O} : 0.02 \text{ Al}_2\text{O}_3 : 1.0 \text{ SiO}_2 : 100 \text{ H}_2\text{O}$. Then, the mixture was transferred into a Teflon-lined stainless steel autoclave and heated in an oven at 443 K for 36 h. Intermediate and final products were subjected to separation by high speed centrifuge (30000 r/min, 30 min, Beckman Avanti JXN-30), washed thoroughly, and dried in a freeze dryer. The ZSM-5 zeolite sample collected in the end of synthesis was denoted as Z_p . The variation of pH in the gel during crystallization process was monitored by testing the liquid phase after separation from the reacted mixture by centrifugation.

Co^{2+} -exchanged zeolites were prepared according to the following procedures. First, 2 g calcined zeolite sample was experienced sodium ion exchange by a NaCl (Sinopharm Chemical Reagent Corporation, 99.8%) solution with weight ratio as follows: 1.0 g zeolite: 1.0 g NaCl: 10.0 g H_2O . This process was performed at 363 K for 3 h and repeated three times before washing. The obtained Na-form ZSM-5 zeolite was dried at 373 K overnight and then dispersed into a 0.05 M $\text{Co}(\text{NO}_3)_2$ solution with a weight ratio of 1:10 and ion-exchanged at room temperature for 6 h under stirring. To achieve complete exchange, the Co^{2+} exchange was repeated 3 times. The final exchanged sample was washed thoroughly and dried at 373 K overnight.

2.1.2 Treatment of ZSM-5 crystals with NH_4F

The parent ZSM-5 zeolite (sample Z_p) was divided into 2 parts: one part (as-synthesized sample) was treated by NH_4F without removing the organic structural directing agent (TPA^+) and the second part (calcined sample) was treated at 823 K in static air for 12 h with a temperature ramp of 6 K min^{-1} . Subsequently the NH_4F treatment was carried out in 40 wt.% ammonium fluoride solution (NH_4F , 96 wt.%) at 323 K under stirring, with a solid/liquid ratio of 1: 30. The

NH₄F treatment time of the as-synthesized ZSM-5 was 4 h, and for the calcined ZSM-5 was 1 or 2 h. The treated zeolites were collected by vacuum filtration, washed with deionized water and dried at 373 K overnight. The sample obtained from the as-synthesized ZSM-5 after treatment with NH₄F will be abbreviated as TPA-Z_F thereafter.

2.1.3 Synthesis and NH₄F etching of ZSM-5-H1 and ZSM-5-H2

The first home-made ZSM-5 zeolite, ZSM-5-H1, was synthesized from an initial gel with a molar composition of 1.0 SiO₂: 0.01 Al₂O₃: 0.25 TPAOH: 8.1 H₂O. First, aluminum nitrate nonahydrate (99 wt. %) was dissolved in an aqueous solution of tetrapropylammonium hydroxide (TPAOH, 25 wt. %) to get a clear solution. Then colloidal silica (40 wt. %, LUDOX HS-40, Sigma-Aldrich) was added slowly into the template-aluminum mixed solution. The resultant mixture was stirred for another 60 min. Then the synthesis gel was loaded to a Teflon-lined stainless steel autoclave. The sealed autoclave was transferred into a preheated air-circulated oven and heated at 443 K under static conditions. After 7 days the autoclave was removed from the oven and quenched immediately with cool tap water. Solid material was recovered by centrifugal separation and washed with distilled water until the pH of the wash was approximately 7.0. The solid product was then recovered and dried at 373 K overnight. The template was removed by calcination at 823 K for 12 h with a ramp of 2 K / min.

The composition (molar ratio) of initial gel for the preparation of the second home-made ZSM-5 zeolite, ZSM-5-H2, was as followed: 1.0 SiO₂ : 0.01 [(CH₃)₂CHO]₃Al: 0.491 TPAOH: 0.118 KOH: 30 H₂O. First aluminum isopropoxide (98 wt%, Fluka) was dissolved in an aqueous solution of tetrapropylammonium hydroxide (TPAOH, 20 wt%, Alfa Aesar) and potassium hydroxide (85 wt%, Sigma-aldrich) to get a clear solution. Another solution was prepared by mixing colloidal silica (40 wt%, LUDOX HS-40, Sigma-Aldrich) with a proper amount of distilled water and added slowly into the template-aluminum mixed solution under stirring. The resultant mixture was stirred for another 60 min. Then the synthesis gel was loaded to a 100 mL Teflon-lined stainless steel autoclave. The sealed autoclave was transferred into a preheated air-circulated oven and heated at 443 K under static conditions. After 48 h the autoclave was removed from the oven and quenched immediately with cool tap water. Solid material was recovered by vacuum filtration and subsequently washed with distilled water until the pH of the wash was approximately 7.0. The solid cake was then recovered and dried at 373 K overnight. The template was removed by calcination at 823 K for 6 h with a ramp of 1.5 K / min.

Figure 1. SEM (A) and TEM (B) images of parent ZSM-5 zeolite (sample Z_p), SEM (C) and TEM (D) images of ZSM-5 zeolite treated with NH₄F (sample TPA-Z_F). Scale bars in A-D are 1 μ m. Illustration of the multiple core-shell structure of zeolite crystals (E), different layers of the core-shell structure are distinguished: R₁ represents the outermost shell (“egg-shell”), R₂ the highly segmented layer in the middle (“egg-white”), and R₃ the innermost layer (“egg-yolk”)

Fluoride medium etching was carried out follows precisely the same procedure as for the NH₄F treatment of the ZSM-5 zeolite in previous section.

2.2 Characterization

The X-ray diffraction (XRD) patterns of as-synthesized and post-treated zeolite samples were collected on a Bruker D8 Advance diffractometer equipped with Cu K α radiation ($\lambda = 1.5418 \text{ \AA}$).

Scanning electron microscopy (SEM) images were taken with JSM-7900F (JEOL) electron microscope equipped with a field emission gun. The cross-section of zeolite samples was prepared by using an ion Beam cross-section polisher (IB-19510CP, JEOL). The zeolite crystals were fixed on a carbon tape prior preparation of the cross-sections. Then the cut samples were coated with osmium (Os) using a Filgen Os coater (3 nm thick) and the element mapping was recorded with a JSM-7900F SEM with an EDS detector (Oxford EDS 170 mm x2). The acceleration voltage, beam current and work distance for the SEM study were 5 kV, 1.5 nA and 10 mm, respectively. In addition, the chemical composition of the zeolites was measured by XRF using an AXIOS-Petro X (PANalytical B.V.). The surface chemical composition (Si/Al ratios) of zeolite crystals was obtained by X-ray photoelectron spectroscopy (XPS) with a PHI 500 spectrometer using Al K α radiation. Transmission electron microscopy (TEM) pictures were taken on a JEM-2100 (JEOL) with an accelerate voltage of 200 kV. Scanning transmission electron microscopy (STEM) images were taken on a JEOL JEM-F200 electron microscope with Gatan Rio 1816 (IS) camera, allowing a point resolution of 1.9 $\text{\AA}$ under STEM mode, equipped with a JEOL SDD EDS detector (100 mm 2×1). All STEM images and EDS spectra were taken under an acceleration voltage of 200 kV.

The porosity of the samples was studied by Ar physisorption performed on an Auto-sorb iq3 (Quanta chrome) at 87 K. The N₂ sorption isotherm of Na⁺ exchanged TPA-Z_F was also performed on the Auto-sorb iq3 (Quanta chrome) at 77 K. The size of particles in initial amorphous gels used for the preparation of ZSM-5 crystals was measured by dynamic light scattering (DLS) using a Malvern Nano ZS instrument.

3. Results

3.1. The multiple core-shell structure of zeolite crystals

The crystalline parent ZSM-5 zeolite (Z_p) with uniform particle size distribution are presented in Figures S1. All individual crystallites show a polycrystalline morphology consisting of densely packed nanosized crystals (Figure 1A and Figure S1B-D). Both the TEM and STEM images show a homogeneous contrast of the zeolite crystals, indicating the absence of textured structures (Figure 1B, Figure 2A-C). The characteristic coffin shape for MFI type zeolite are shown in Figure S1D.

Figure 2. STEM images of Z_p (A) and TPA- Z_F (D), and STEM-EDS mapping images of Z_p (B: Si, C: Al) and TPA- Z_F (E: Si, F: Al), Scale bar = 2 μm .

Figure 3. Cross section SEM images of the parent ZSM-5 zeolite crystals (sample Z_p , A-C) and NH_4F treated ZSM-5 zeolite crystals (sample TPA- Z_F , D-F) at different magnification, scale bars: 10 μm (A), 1 μm (B, D and E), 200 nm (C and F). The white arrows indicate the presence of voids in the zeolite crystal volume.

The polycrystalline ZSM-5 zeolite (Z_p) was treated by NH_4F without removing the organic template (TPA^+). The chemical treatment of the template-containing zeolite results in a zeolitic material (TPA- Z_F) with preserved crystallinity (Figure S2) and a distinct core-shell structure (Figure 1C, Figure S3). While the core part (R_2 , Figure 1C) appears as an assembly of numerous nano-sized nanoparticles, the shell (R_1 in Figure 1C) is more united, with a homogeneous orientation of crystals with an even thickness. The zeolite crystals formed a polycrystalline shell (outermost “egg-shell”), with a thickness of about 1 micron (Figure 1C, Figure S3). Additionally, two layers (R_2 and R_3) can be clearly seen of the crystals (Figure 1D, Figure 2D-F and Figure S4). R_2 represents a highly segmented layer in the middle (“egg-white”) of the TPA- Z_F crystals, while the R_3 represents the innermost layer (“egg-yolk”). The core (R_3 in Figure 1) is the most integrated one with either an elliptical or rectangular shape (Figure S4). This part, with a homogeneous and striking contrast, reveals the less porous nature of this area (Figure 1D, Figure 2D-F and Figure S4). To summarize, the TPA- Z_F zeolite has a distinct multiple core-shell structure as schematically presented in Figure 1E.

Details of the architecture of the multiple core-shell structures are provided by cross-section of Z_p and TPA- Z_F

crystals (see Experimental section). The structural details of these samples are revealed using ultra-high-resolution FE-SEM performed on coated (Figure 3D, E) and uncoated (Figure 3A-C and F) samples with a conductive layer. The multi-layer core-shell structure of TPA-Z_F zeolite is clearly seen in the cross-section SEM pictures shown in Figure 3D-F. This observation is consistent with the TEM and STEM results (Figure 1D, Figure 2 and Figure S4). Thus all the SEM, TEM, and STEM results confirmed the egg-like structure with multiple core-shell architectures of the TPA-Z_F zeolite.

No core-shell structure in the parent ZSM-5 zeolite (sample Z_P) is observed, although the cross-section SEM pictures contain a white “O-ring” (Figure 3A, B). Obviously, the NH₄F treatment caused the formation of the multiple core-shell structure of sample TPA-Z_F. The white “O-ring” area can be considered as the boundary separating two zeolitic zones with different solubilities in fluoride media. This finding is based on the perfect matching of size and morphology of crystals of Z_P and TPA-Z_F shown in Figures 1-3 and Figures S1, S3, S4. The dissolution front propagation is inward since the dissolution of the periphery of the middle layer (R₂) is notable (Figure 1C-D, Figure 3D-F).

3.2 The spatial distribution of elements in zeolite crystals

Table 1. EDX relative content of elements at selected zones (Figures 4A, C) for samples Z_P and TPA-Z_F (errors shown in parentheses).

Spectrum Label	C (± 0.51)	Na (± 0.24)	Al (± 0.32)	Si (± 0.79)	Si i/Al
1 (Z _P)	6. 59	0. 36	0. 84	30 .31	3 4.8
2 (Z _P)	5. 75	0. 47	1. 62	29 .33	1 7.5
3 (Z _P)	4. 44	1. 14	2. 19	28 .26	1 2.4
4 (Z _P)	9. 56	1. 31	1. 47	27 .92	1 8.3
1 (TPA-Z _F)	15 .01	0. 19	0. 56	23 .96	4 1.3
2 (TPA-Z _F)	16 .58	0. 18	0. 66	23 .51	3 4.3
3 (TPA-Z _F)	48 .56	0. 00	0. 56	13 .50	2 3.2
4 (TPA-Z _F)	48 .96	0. 05	0. 76	13 .51	1 7.1

Figure 4. SEM-EDX mapping of the parent (Z_p) and post treated ($TPA-Z_F$) ZSM-5 zeolites (Scale bar = 2.5 μm): (A) SEM image of sample Z_p , (B) EDX mapping of sample Z_p , (C) SEM image of sample $TPA-Z_F$ and (D) EDX mapping of sample $TPA-Z_F$. The EDX mapping presented in (B) and (D) show overlapping of different elements: sodium (blue), carbon (red) and aluminum (green). Inset: point analysis of the chemical composition in zones 1,2,3 and 4 performed and results are summarized in Table 1. Note: there is no one-to-one correspondence between Zones R_1 , R_2 , and R_3 in Figures 1 and 3 and Zones 1, 2, 3, 4 shown here and in Table 1.

The Si/Al ratio of the parent ZSM-5 (sample Z_p) is 20.3, according to the XRF analysis. It increases to 23.5 for sample $TPA-Z_F$ obtained after the NH_4F treatment. The “dealumination” phenomenon during the chemical treatment of zeolites in concentrated fluoride medium was already reported.^[28] However, the used NH_4F treatment is not Si or Al biased.^[7,29,30] This motivated us to perform mapping of spatial elements distribution within zeolite crystals before and after the NH_4F treatment since not a selective extraction of elements from the parent zeolite is expected. An EDX mapping of coated zeolite crystals with a 3 nm thick Os layer is carried out. Os, instead of other conductive layers (Au, C, Pt) was applied for enhancing the conductivity of the specimen and for the precise detection of the carbon signal. The penetration depth was 100 nm under the applied conditions (see experimental section). The relative content of elements where the analysis was performed was normalized and calculated in atomic % (Table 1). The corresponding SEM-EDX mapping and elemental point analysis data are shown in Figures 4, S5–S7.

The EDX mapping results provide the following important information: (i) All crystals of the parent sample have higher Si content in the core part, then the Si/Al ratio decreases outward. This observation is valid for all crystals regardless of their particle sizes (Figure 4A, B). This tendency is clearly illustrated from the point analysis showing that the Si/Al ratio decreased from 34.8 to 12.4 from zone 1 to zone 3 (Table 1). At the same time, there is a systematic decrease of carbon and an increase of Na from the core to the periphery of the crystals (Figures S5, S6). (ii) Similar zoned distribution of Si and Al was recorded for the post-treated zeolite $TPA-Z_F$ (Figures 4C, D and Figures S5, S7); a general increase of the Si/Al ratio of the sample is measured (Table 1). Both the EDX and XRF show similar results. (iii) All zones of the treated sample, with different degrees of dissolution, indicate lower Na^+ content than the parent sample (Table 1). Especially, the selected zone labelled as “3” in Figure 4C has no essential Na^+ (see Table 1). This zone 3 corresponds to the “ R_2 ” shown in Figures 1 and 3. This observation is important, in particular, considering that the domain size of zeolite crystals is still about 50 nm large (~ 25 unit cells) despite being heavily dissolved (Figure S4).

This result points out that most of the charge compensating cations (Na^+) in the zeolite are exchangeable, even though the TPA^+ counter cations block parts of zeolite framework. (iv) The TPA^+ concentration increases substantially in the sample after the NH_4F treatment (TPA-Z_F), especially in the R_2 zone (Table 1, Figures S5, and S7). It is worth noticing that the samples were washed thoroughly after the NH_4F treatment. Thus, the deposition of TPA^+ containing salts on the zeolite crystals is not due to insufficient washing.

4. Discussion

The structural characteristics of a zeolite crystal dictates its dissolution behavior during the post-synthesis treatment and *vice versa*.^[7,28] Based on the results presented above, a detailed discussion will be held about the underlying mechanism leading to the selected-area dissolution behavior, and about the ultimate synthetic cause for the core-shell structure and Al-zoning formation.

4.1. The mechanism leading to selected-area dissolution

A) Defect-zoning

The spatially inhomogeneous dissolution of zeolite crystals has been reported by us before. Namely, the inner part of zeolite crystals is preferentially dissolved, while an outermost crust is resistant to NH_4F treatment.^[30] However, such unique zeolite crystals with a multiple core-shell structure was never reported before. We believe that two factors, in addition to the NH_4F treatment, are responsible for the formation of this unique multiple core-shell architecture of ZSM-5 zeolites. First, the location of TPA^+ as a charge balancing cation in the MFI zeolite framework could play an important role. The dissolution of calcined Z_P zeolite (free of TPA^+) was carried out under the same NH_4F treatment conditions. In this case, the dissolution of zeolite crystals was much faster in the absence of TPA^+ . This can be confirmed by the low product yield even when the treatment time was reduced by a half or even more. For example, the sample yield is 50% after 1 h NH_4F treatment in the absence of TPA^+ . In the case of the as-synthesized zeolites containing TPA^+ , the product yield is 55% after 4 h NH_4F treatment. The calcined ZSM-5 zeolite was deeply dissolved after the treatment, as shown in Figure S8. The outmost shell is totally removed (Figure S8A). The R_2 zone is almost fully removed after the treatment (Figure S8C). Even the core zone was highly etched, as shown in the SEM (Figure S8B) and TEM (Figure S8C, D) images. While sample TPA-Z_F containing the TPA^+ treated by NH_4F even for longer time contains intact core (Figures 2D, 3E and S4). Apparently, the presence of TPA^+ suppresses substantially the dissolution of zeolite crystals in the NH_4F medium. TPA^+ cations occupy the intersection position of straight and sinusoidal channels of MFI zeolite during crystallization.^[31] Thus the presence of TPA^+ disturbs the diffusion of active fluoride species inside the zeolite, and directs the dissolution possibly only from the external surface of crystals or from the extended interface between large intergrown particles (see more examples in section 3.3 below), following a reverse “layer-by-layer” dissolution mechanism.^[30]

Alternatively, the dissolution process can spread via Na^+ -rich zones. Namely, now that most of the Na^+ is exchangeable, the fluoride treatment along the available ion exchange sites is the most plausible alternative. Previously, we have identified isolated rectangular cavities as large as 20 nm surrounded by pure zeolitic walls as a result of the preferential removal of hidden nanosized domains by NH_4F treatment.^[7] This is a sound proof that active fluoride species can diffuse, via the available micropores of MFI framework, into the inner part of zeolite crystal and dissolve the crystals from inside based on the weak zones present.^[28,30]

While the presence of TPA^+ suppressing the dissolution of zeolite crystals is rationalized and the possible tuning effect of charge compensating cations on zeolite dissolution behavior is discussed, these results cannot explain the biased

dissolution front yet. As at the beginning of dissolution, the spatial distribution of Na^+ and TPA^+ cations in the narrow region to be removed can be considered as homogeneous, and there is an equal chance for the adsorption of TPA^+ on either side of the dissolution front. Moreover, the R_1 zone should dissolve more if the Na-zoning dominates the dissolution behavior, as the Na content is higher in the R_1 than in the R_2 zone (Table 1, Figure 4). The fact that the R_2 zone is dissolved much more than R_3 suggests that the dissolution front is inward-pointing.

This result suggests the second possible cause for forming a unique core-shell structure that can be the defect sites. We already reported that the dissolution in NH_4F medium starts preferentially from defects, including the interface between different crystallites domains.^[7,29] Therefore, the R_2 zone has a much higher number of defects sites than the R_1 zone. In agreement with this, the R_1 zone shows a much larger coherent domain size than the R_2 zone (Figure S9). A careful inspection of the uncovered cross-section of Z_P reveals the presence of meso-sized pores in the volume of crystals (Figure 3C). Moreover, it seems most, if not all, of the meso-sized holes are distributed inside of the crystals and pointed with the area surrounded by the “O-ring” (Figure 3C). Whether the mesopores influence the crystal dissolution in NH_4F solution is not clear. We will provide a strong argument (*vide supra*) that the presence of such meso-sized pores is a clear evidence that the “ R_2 ” zone is a defect and/or local-strain rich zone, being vulnerable to NH_4F treatment. In the present work, we named this phenomenon as a “defect-zoning”.

B) Al-zoning

In addition to the defect-zoning discussed above, the EDX mapping reveals an Al-zoning in the ZSM-5 zeolite (Figure 4 and Table 1). Such an inhomogeneous distribution of Al in zeolite crystals is not new. Indeed, Al-zoning in FAU,^[32,33] TON,^[34] MOR,^[35] and especially for MFI type zeolites^[22,36-39] has been reported. A gradient distribution of framework Al increasing from the core to the rim is recorded often. However, the connection between Al-zoning and the spatial arrangement of organic and inorganic structural directing cations is not discussed up to now. In the present work, we show that the Al gradient distribution in the parent ZSM-5 sample is in good accordance with the spatial distribution of C and Na. Specifically, higher Si/Al ratio corresponds to higher TPA^+ and lower Na^+ cations, and conversely, lower Si/Al ratio corresponds to lower TPA^+ and higher Na^+ cations (Table 1). Thus, the Na^+ cations favor the incorporation of Al in the MFI framework structure.

We further show that the applied NH_4F treatment results in a zeolite with higher Si/Al ratio than the parent sample due to the substantial dissolution of the R_2 layer. The “unusual” Al-biased dissolution phenomenon, combined with the regioselective dissolution manifests that the dissolved part is relatively rich in Al. This can also be clearly seen from the difference in the chemical composition before and after NH_4F etching (Table 1). Noteworthy, the dissolved part should also correspond to a relatively Na^+ -richer and TPA^+ -poorer zone in the parent sample. Consequently, the Na^+ -occupied sites are more accessible, providing the etching fronts during the NH_4F etching of the R_2 layer. This would mean that TPA^+ (Si)-richer and Na^+ (Al)-richer zones are alternatively distributed in the volume of the R_2 layer, especially when the spatial homogeneity of the interstitial porosity pattern in this part is taken into consideration (Figure 1, Figure S4). These interstitial pores penetrated deep towards the R_3 zone, corresponding to the removed parts (Figure 1C-D and Table 1). This observation is in accordance with the comment of the high TPA^+ content in R_2 region of TPA-Z_F (Figure 4D). The probing of the porosity by N_2 physisorption revealed that the accessible micropore volume of TPA-Z_F is almost zero even after Na^+ -exchange (supporting information) (Figure S10). This is a clear sign that the micropores are practically blocked by TPA^+ .

Interestingly, such a spatial alternation of organic-cation-rich and inorganic-cation-rich zones in zeolite crystals

is not an individual observation (more examples are provided in section 3.3). These findings are very important since there are great scientific and technological interests in the development of synthetic approach towards the incorporation of site-specific heteroatoms in zeolite framework.^[40] Especially, the combination of inorganic and organic cations was explored as a prevalent way to adjust the location of Al in specific framework tetrahedral positions.^[31,41,42] Our findings raise an important question regarding the spatial distribution of these “site-specific” heteroatoms at the mesoscale. In the present work, Co^{2+} was used to probe the Al distribution in the zeolite framework. The results show that the Co/Al ratio determined by XRF is 0.37 for the Co^{2+} -exchanged Z_p. It decreased to 0.23 for sample TPA-Z_F. This decreased Co^{2+} exchange capacity is a clear indication that the removed Al-rich zone is favorable for the accommodation of Co^{2+} cations. Thus, the Al sitting and Al zoning, originally discussed at the micro- and macro-scales, respectively, must be reconsidered carefully to understand the sitting and distribution of Al in zeolite frameworks.

4.2 Defect-zoning and Al-zoning: a synthesis perspective

At this stage, a comprehensive understanding of the internal architecture of zeolite crystals and the spatial distribution of atoms building the structure is related with the synthesis conditions. Therefore, the zeolite synthesis was thoroughly investigated.

A) Defect-zoning

The ZSM-5 zeolite was synthesized using both TPA^+ and Na^+ cations as structural directing agents. After the formation of a homogeneous solution consisting of both TPA^+ and Na^+ templates, the aluminum nitrate was added. The addition of the silica source (TEOS) after the complete dissolution of aluminum nitrate followed by hydrolysis resulted in the formation of homogenous sol comprising ultra-small nanosized aluminosilicate species (Figure S11). Prior to the hydrothermal treatment, the pH of the sol was 11.1. After 2 h crystallization at 443 K, the solid products remain amorphous (Figure S12) containing uniform in size nanosized particle (Figure S13). The first crystalline particles appear after ~3 h hydrothermal treatment; the particles do not have defined morphology until 4 h and they tend to form disordered floccules (Figure S14). Occasionally, we can find some particles with a rectangular shape that can be either amorphous or partially crystalline (Figure S14D). In line with the TEM observation, the XRD reveals the appearance of a crystalline product after 4h (Figure S15). This is described as the first stage of the zeolite crystallization where the shaped particles contain the core R₃ zone.

During the crystallization process, the pH of the suspension is increasing (Figure 5), which is favorable for increasing the supersaturation. As a result, the growth rate increases abruptly, resulting in crystals with large voids in a specific zone indicated by arrows in Figure 3C, i.e. in the R₂ zone in the middle part of the crystal. At this growth stage, the crystallinity of the solid products increases sharply (Figures 5, S12, S15 - S17), but the shape of zeolite particles is mostly irregular (Figure S18). The observed defect-zoning of the ZSM-5 crystals as described above is attributed to the aggregated growth in the second stage of zeolite crystallization. This stage is characterized by fast crystal growth, which could be not favorable for the surface relaxation of the particles after the oriented attachment events^[14], leading to the formation of layers rich in defects and local strains.

At the end of the second stage, the nano-particles are mostly consumed (Figure S19A), but the high supersaturation of the crystallizing suspension is still retained. In the next third stage, the agglomeration process slows down, but the aggregates continue to grow mainly via the addition of lower-weight aluminosilicate species.^[14] The stage resulted in the formation of highly crystalline ZSM-5 zeolite (Figures 5) with a regular morphology (polyhedrons) and specific crystal faces (Figure S19B). At this stage, the nutrients are fully consumed, and the crystallization medium is in a dynamic equilibrium. The zeolite crystals have a multilevel core-shell structure, where each level corresponds to a particular crystallization stage. We noticed that the “egg-shell” structure (Figures 3D, 3E and Figure S3C) can be further subdivided in two layers. This can be attributed to the Ostwald ripening in the inhomogeneous and dynamic system.

Figure 5. Relationship between relative crystallinity of ZSM-5 and the pH of the precursor suspension subjected to hydrothermal treatment at 443 K as a function of crystallization time.

B) Al-zoning

The Al-zoning in the present work has two-fold origin. (part B in section 3.1). The first is related to the classical gradient increase of framework Al content from the core to the rim of the crystals. The possible reason for this specific Al-zoning formation is as follows. During the zeolite synthesis, the precursor species go through several intermediate states, thus contributing to the aggregative growth of crystallites.^[12] Si-rich parts easily dissolve in alkaline medium compare to Al species. Probably, the higher solubility facilitates the active evolution of the Si-rich nanoparticles, and promotes the preferential nucleation of zeolites in these silica-rich parts.^[43] Thus the Si/Al ratio decreases gradually from the core to crystal periphery; these experimental findings are in a good agreement with previous reports.^[22,44] The Si/Al ratio at the crystal periphery is slightly fluctuated (Table 1, Figure 4A). As determined by XPS, the Si/Al ratio is around 14.8. This is another indication that the crystallization is dynamically equilibrated, and the Si/Al ratio at the periphery of zeolite crystals could deviate slightly.^[43] The second Al-zoning refers to the proposed alternation of TPA^+ (Si)-richer and Na^+ (Al)-richer zones within the same zeolite crystal. This is possible if we assume that the new crystallization event always is initiated in the relatively TPA^+ -rich zone, considering that TPA^+ is a strong template for the MFI zeolite formation. This points to the heterogeneity of the hydrogel containing the complex mixture of Si, Al, Na^+ , and TPA^+ . The complexation between aluminosilicates and (in)organic cations can be intrinsically heterogeneous at a mesoscale due to the size and charge density difference between TPA^+ and Na^+ . Accordingly, a similar-sized amorphous aluminosilicate

entity (particles or low-weight molecules) can accommodate a higher number of Na^+ and Al. These entities have a balanced local structure that can be preserved in the final crystallites.

4.3. Are the defect-zoning and Al-zoning general phenomena?

The observations above encourage an investigation on whether the finding of defect-zoning and Al-zoning are a general phenomenon or not. For this purpose, we revisited the NH_4F etching of the two commercial ZSM-5 zeolites, which we have studied before.^[7] In addition, we synthesized two ZSM-5 zeolite samples using either solely TPAOH (ZSM-5-H1) or a combination of TPAOH and KOH (ZSM-5-H2) as structure-directing agents. Then the same NH_4F etching was carried out on the zeolites before and after removing the organic template (Supporting Information). K^+ was specifically selected since it is considered as a structure-breaking cation in the ZSM-5 zeolite synthesis.^[45]

The main findings from the dissolution studies are summarized here. For the two commercial samples, while they are already in NH_4^+ -form (ZSM-5-II offered by Clariant, Si/Al = 21) or H-form (ZSM-5-I from Grace Davison, Si/Al = 16) with the synthesis history unknown, the outer layers of the zeolite crystals are always more resistant to NH_4F etching^[30] (Figure S20). Although there are no distinct boundaries separating different crystal layers as mentioned above, the sharp difference in solubility between crystal interior and outer layers is a clear indication for defect-zoning and a different crystallization behavior.^[30] The time-resolved dissolution of these two samples didn't change their Si/Al ratio.^[7]

The NH_4F etching of the calcined ZSM-5-H1 shows similar selected-area dissolution behavior,^[7] characterized by substantially dissolved crystal interior and less impacted rim (Figures S21-S22) with a marginal change of Si/Al ratio from 44.8 to 43.5. In contrast, the NH_4F etching of the as-synthesized ZSM-5-H1 sample resulted in a greater change of the Si/Al ratio (44.8 vs 40.4). The etched ZSM-5-H1 sample was segmented along extended grain boundary, while the bulk crystals are largely preserved due to the protection of the TPA^+ cations. Noticeably, the core of crystals is preferentially removed (Figures S23-S24). Putting all together, it would mean that the preferentially removed core part is relatively Si-rich, pointing again to the preferential nucleation in the Si-rich zone. The ZSM-5-H2 zeolite was also treated by NH_4F with and without the protection of TPA^+ . Again, the dissolution of the calcined sample changes marginally the Si/Al ratio, which is in agreement with the previous results.^[7] On the other hand, the dissolution of the as-synthesized ZSM-5-H2 sample increases the Si/Al ratio from 41.4 to 55.1. Moreover, the etched sample shows a distinct regioselective dissolution pattern and a core-shell structure (Figure S25), similar to the ($\text{TPA}^+ + \text{Na}^+$) system but on a larger scale. Noting that in principle, only the freely exchangeable K^+ occupied sites are available etching pits as the protective effect of TPA^+ has been repetitively confirmed.

These results show that, while the distinct multiple core-shell structure (Figure 1) might be case-specific, defect-zoning, and Al-zoning are phenomena that can be generalized. The distinction of the multiple core-shell structure reported here points toward a three-stage crystallization process. Nucleation will be favored by the stronger structural directing cations in the Si-rich region. Depending on the geometric and electronic properties, Al zoning at both macro- and meso-scale will be induced. Depending on the supersaturation of the crystallizing system, defect-zoning can be settled or alleviated.

5. Conclusion

In the present work, the inner heterogeneity of zeolite crystals as defect-zoning and Al-zoning at both macro- and meso-scales is revealed. NH_4F etching is used as an unbiased tool for structure disassembly of ZSM-5 zeolite crystals with (as-synthesized) and without (calcined) organic structural directing agent (TPA^+). As revealed by the NH_4F etching, the as-synthesized pseudo-single ZSM-5 crystals have a defect-zoning resulting essentially in an egg-like multiple

core-shell structure. The innermost core, the “egg-yolk” part of the multilayer structure, is surrounded by a zeolite layer rich in defects, which forms the “egg-white” part in the middle of the pseudo-single crystal. It is preferentially dissolved by NH_4F as a result of the higher defect concentration in this layer. The outermost part of the zeolite crystals, the “egg-shell”, is more resistant than the “egg-white” thanks to the lower defect content.

Several studies have reported on the etching of ZSM-5 zeolite leading to similar Al-zoning.^[38, 46] Further, we revealed that the compact core has the highest content of Si and TPA^+ and the lowest concentration of Na^+ . Both the Si/Al ratio and TPA^+ content keep decreasing from the core to the crystal periphery, accompanied by a continuous increase in Na^+ concentration. Thus, a clear map of spatial elements distribution was obtained, and the relation between Al-zoning and charge-compensating cations (structure-directing agents) was observed for the first time.

Both the defect-zoning and Al-zoning are bound to the crystallization in a substantially inhomogeneous and dynamic supersaturation environment. The crystallization process of zeolite is described as a three-stage process: Stage 1: nucleation starts preferentially in the Si-rich part, templated by TPA^+ , due to the higher solubility of silica in the alkaline medium; Stage 2: rapid amorphous-to-crystalline transformation process resulting in a fast increase of the apparent crystallinity, and fast accumulation of units including nano-particles, low-weight molecules, etc. This fast crystallization is combined with a delay in their post-attachment to the growing crystals resulting in the formation of defects in the zeolite, thus making them vulnerable to NH_4F treatment. Meanwhile, more Al is incorporated in the zeolite framework due to the higher solubility of the Al-containing species with the increased alkalinity of the suspension. Thus the Na^+ content in the zeolite crystals increased accordingly to compensate the framework negative charges. Stage 3: the last state of crystallization, is a near-equilibrium process dominated via layer-by-layer crystal growth, leading to the formation of the surface crust of the crystals with characteristic MFI morphology.

The exploitation of the dissolution behavior of several ZSM-5 zeolites synthesized in systems containing different templates ($\text{TPA}^+\text{-Na}^+$, pure TPA, $\text{TPA}^+\text{-K}^+$) further supports the ubiquitous defect-zoning and Al-zoning phenomena. The in-depth understanding of zeolite dissolution behavior, the inner heterogeneity and chemical gradient (elemental distribution) of zeolite crystals, and the deduced zeolite crystallization mechanism provide valuable information for further tailored-design of zeolite crystals with pre-determined properties.
