Abstract

This document presents complementary experiments on the published algorithm of Thick Line Segment Detection with Fast Directional Tracking. The main paper is actually published at ICIAP 2019 [2]. First tests compare the performance of the detector with and without adaptive directional scans (ADS) and assigned thickness control (ATC). On the detector without ADS, the fine tracking step must be performed twice to get less risk of growing blurred segment escape from the scan strip.

1 Experimentations on synthesized images

These tests compare both versions on a set of 1000 synthesized images containing 10 randomly placed input segments with random width between 2 and 5 pixels. The absolute value of the difference of each found segment to its matched input segment is measured. On these groundtruth image, the numerical error on the gradient extraction biases the line width measures. This bias was first estimated using 1000 images containing only one input segment (no possible interaction) and the found value (1.4 pixel) was taken into account in the test. Results are given in the following table.

If we call $S$ the count of pixels of all input segments in an image, $D$ the count of pixels of all output blurred segments, and $I$ the count of successfully detected pixels ($D \cap S$), the given measures are:

1. the count of output blurred segments,
2. the count of output long (> 40 pixels) blurred segments,
3. the count of undetected input segments,
4. the precision $P = I/D$,
5. the recall $R = I/S$,
6. the F-measure $F = 2.P.R/(P + R)$,
7. the absolute value of the width difference between matched output segments with input segments,
8. the absolute value of the angle difference between matched output segments with input segments.
Figure 1: Evaluation on synthesized images: two of the randomly generated images (a,d), bounding lines of output blurred segments without (b,e) and with (c,f) ADS and ATC concepts.

Table 1: Measured performance on both Figure 1 image examples and on a whole 1000 synthesized images set, without and with adaptive directional scans and assigned width control.
2 Experimentations on real images

Next tests compare both versions on real images:
- first the set of 102 images of York Urban data base [1] augmented with manually
  extracted groundtruth lines (an example in Fig. 1),
- then selected images for more detailed visual analysis (Fig. 3 and Fig. 4).

Reported measures in Tab. 2, Tab. 3 and Tab. 4 are execution time $T$, groundtruth cov-
ering ratio $C$ (only for the York Urban data base), number of output line segments $N$,
mean length of output line segments $L/N$, and mean thickness of output line segments $W$.

Shorter execution time is achieved with the new concepts. Detected blurred segments
are shorter but thinner. Obviously the constant assigned thickness augments the proba-
bility to extend the segments with outlier edge points as can be noticed in the detail of
office (Fig. 3) and castle images (Fig. 4). Moreover, brick joints are better detected in
castle image.
