Abstract

A novel approach for the synthesis of Fe(0) nanoparticles (NPs) with tunable sizes and shapes is reported. Ultrasmall Fe(0) NPs were reacted under mild conditions in the presence of a mixture of palmitic acid and amine ligands. These NPs acted not only as preformed seeds but also as an internal iron(II) source that was produced by the partial dissolution of the NPs by the acid. This fairly simple approach allows a strict separation between the nucleation and the growth steps. By changing the acid concentration, a fine tuning of the relative ratio between remaining Fe(0) seeds and iron(II) reservoir was achieved, giving access to both size (from 7 to 20 nm) and a shape (spheres, cubes or stars) control. The partial dissolution of the ultrasmall Fe(0) NPs into iron(II) source and the successive growth was further studied by using combined TEM and Mössbauer spectroscopy. The successive corrosion, coalescence, and ripening observed could be understood in the framework of an environment-dependent growth model.

Key words : Moessbauer spectroscopy, iron, magnetic properties, nanoparticles, seeded growth

TOC

Taking benefit of nanoparticle ripening, we report the use of ultrathin Fe(0) nanoparticles as a new iron source for the size and shape control of metallic NPs. Playing with the atmosphere conditions, isotropic growth or oriented attachment can be selectively favored. The key role played by the hydrogen in the final faceting is evidenced, leading to highly crystalline Fe nanostars or nanocubes.

INTRODUCTION

Magnetic nanoparticles (NPs) are objects of choice for a wide range of applications,^[1] such as data storage,^{[2],[3]} catalysis,^[4] and biomedical ones.^{[5],[6]} Among the different properties sought, the potential overheating of the nanoparticles in presence of an alternate magnetic field received tremendous interest due to its implication on Magnetic Field Hyperthermia (MFH) treatment^[7] and thermally-assisted catalysis.^{[8],[9]} To benefit from optimized heating properties, high saturation magnetization (M_S) materials are mandatory.^{[10],[11]} Metallic Fe NPs exhibit magnetization far above their oxide counterparts. However, due to the reactivity of iron towards oxidation, synthesis and stabilization of such fully metallic nanoobjects remains a challenge.^[12] The thermodecomposition of $\text{Fe}(\text{CO})_5$ in the presence of long-chain ligands has been used in several occasions.^{[13],[14]} However, the magnetic properties of these NPs are usually degraded compared to bulk values due to synthesis by-products such as carbon and oxygen impurities. Recently, alternative precursors such as $\text{Fe}(\text{oleate})_3$,^[15] $\text{Fe}(\text{C}_5\text{H}_5)(\text{C}_6\text{H}_7)$,^[16] or $\text{Fe}\{\text{N}[\text{Si}(\text{CH}_3)_3]_2\}_2$,^[17] leads to NPs exhibiting high magnetization and narrow size distribution. Yet, the control of the nanoparticle size and shape, and thus the physical properties of the objects have scarcely been addressed.^[18] In contrast to Co and CoNi alloy, for which anisotropic shapes could be reached by tailoring the adopted crystalline structure,^{[19],[20]} such morphological control was not yet achieved for Fe, which exposes a body centered cubic structure. To reach the nanoscale design required for the fine tuning of both size and shape of Fe NPs, a deep understanding of the underlying nucleation and growth mechanisms is needed.

Following an organometallic approach, we were able to produce nanoparticles with a mean diameter ranging between 1.5 and 9 nm,^[18] and single crystal nanocubes self-organized into micrometric superlattices by reduction of $\{\text{Fe}[\text{N}(\text{SiMe}_3)_2]_2\}_2$ ($\text{Me} = \text{CH}_3$) in presence of long chain acid and amine under H_2 at 150°C .^[17] Thanks to a detailed kinetic study and the

characterization of the intermediate complexes formed in-situ, among which Fe carboxylate, we could propose a complex 3-step mechanism to rationalize the synthesis. First, as classically invoked, nucleation proceeded. Then, a growth occurred concomitantly to a coalescence step, in presence of an amine rich environment. Finally a growth-ripening step is observed, induced by the release of carboxylate. Playing with the experimental conditions one can favor any of these three steps. Lowering the reaction temperature or changing the amine/acid allowed favoring the coalescence, yielding stars^[18] and porous cubes.^[21] Replacing carboxylic acid by ammonium chloride salt changed the iron intermediates formed and thus fastened the reaction kinetic, yielding larger spheres and cubes.^{[22],[23],[24]} To go beyond these results, we now need to gain control on the initial nucleation step. In the literature, the use of preformed seeds, in the so-called seeded-growth process,^{[25],[26]} leads to the strict separation of the nucleation and the growth processes. Pt seeds have been successfully used to promote the heterogeneous growth of Fe NPs by thermodecomposition of $\text{Fe}(\text{CO})_5$.^{[13],[27]} Recently, our group reported the overgrowth of Fe cubes onto preformed Co nanorods using $\{\text{Fe}[\text{N}(\text{SiMe}_3)_2]_2\}_2$.^[28] Here, we propose a different approach where ultrasmall Fe(0) NPs of 1.5 nm^[29] were used both as seeds and as Fe source, the idea behind consisting in taking advantage of the ripening step observed in the presence of carboxylic acid. The key role played by the hydrogen was evidenced by a combined transmission electron microscopy (TEM) and Mössbauer spectroscopy study.

RESULTS & DISCUSSION:

1.5 nm nanoparticles (NPs) were obtained by decomposing $\{\text{Fe}[\text{N}(\text{SiMe}_3)_2]_2\}_2$ at 150°C under 3 bars of dihydrogen.^[29] These ultrasmall particles were further used without

any purification as reactive Fe(0) seeds. Ageing these seeds at 150°C with a mixture of ligands (palmitic acid, PA and hexadecylamine, HDA, Figure 1) under controlled atmosphere (H₂ or Ar) yield larger nanoparticles. Contrarily to the classical seeded-growth method used, no external iron source was added, the reactive Fe(0) seeds initially introduced being partly dissolved to form stable iron(II) species, they acted both as seeds and iron source, as further detailed below.

Figure 1. Schematic view of the aging process of reactive Fe(0) seeds in presence of amine/acid ligand mixtures. Depending on the atmosphere, a growth or a complex coalescence/ripening can be observed.

The effect of the acid concentration on the aging process of Fe(0) seeds was studied at 150°C under H₂ atmosphere while keeping the amine concentration constant ([HDA] = 100mM). In presence of 50mM of palmitic acid, 7.0 ± 0.1 nm NPs were observed after 7 days of reaction at 150°C. Increasing the acid concentration to 75mM yielded slightly larger NPs exhibiting a mean diameter of 8.0 ± 0.1 nm NPs. In presence of an equi-proportion of acid and amine (100mM), the reaction was fastened as revealed by the important precipitation of 10.2 ± 0.1 nm NPs onto the magnetic stirrer after only 48h of ageing (Figure 2 and S1).

The final state of the ageing process, corresponding to the full reaction of the preformed Fe(0) seeds was never achieved. Indeed, unreacted seeds remained even after extended reaction

time (up to 28 days) as characterized by TEM and zero-field cooling/field cooling magnetic measurements (Figure S2).

Large Fe(0) NPs could be easily retrieved from the reaction media using conventional centrifugation process. For instance, 10.2 nm NPs could be sorted and further characterized (Figure S3). The particles are highly crystalline and exhibit the expected bcc-Fe structure as revealed by X-Ray Diffraction (Figure 2e). Magnetic measurements performed at low temperature revealed a saturation magnetization of $215 \text{ Am}^2\text{kg}^{-1}$, similar to the bulk value (Figure 2f). Mössbauer spectroscopy confirmed a pure Fe(0) composition, as revealed by the single sextet observed (Figure S3b).

Figure 2. Transmission electron microscopy (TEM) images of Fe NPs obtained from a) Fe(0) seeds after an aging process of (b-c) 7 days and d) 2 days in presence of 100mM of HDA and b) 50, c) 75 and d) 100 mM of PA. Scale bar corresponds to 50 nm. e) XRD pattern and f) Hysteresis cycle measured at 2K after a 5T field-cooling of the 10 nm spheres observed in d) after purification process. As inset : zoom of the +/- 400 mT region, evidencing the absence of any exchange bias. The black lines in e) correspond to the bcc-Fe reference pattern (PDF-00-006-0696).

Starting from metallic Fe(0) seeds as new iron source for the synthesis of large NPs, the question of the role of H₂, classically used as a strong reducing agent, naturally rose up. Therefore a comparative study in absence of H₂ was performed. Fe(0) seeds were aged during 48h at 150°C under Ar in presence of an equi-concentration of PA and HDA (100mM). While 10.2 nm NPs were previously obtained under similar condition in H₂ atmosphere, large star-like shaped NPs were synthesized (Figure 3a). High resolution transmission electron microscope (HREM) revealed that these Fe NPs were single-crystalline but they do not exhibit any preferential exposed facets (Figure 3b).

Similar ill-defined nanoparticles were previously observed as intermediate states prior to the stabilization of Fe nanocubes during the direct reduction of {Fe[N(SiMe₃)₂]₂}₂.^[28] We invoked at that time an oriented-coalescence phenomenon in presence of an amine rich environment to explain the growth of such objects. Since we previously reported a successive ripening process which promoted the stabilization of {100} facets on Fe nanocubes, we tried to further extend the reaction time on our star-like shaped NPs up to 96h at 150°C under Ar. However, the stars were fairly stable and no sign of shape evolution was detected (Figure S4).

On the contrary, allowing the star-like shaped NPs to react under H₂ at 150°C yielded faceted NPs (Figure 3c-d). HREM image and the corresponding Fourier transform (FT) confirmed that the faceted stars remained single-crystalline and clearly exhibit mostly {100} facets (Figure 3d and S5). The additional peaks appearing in the FT were due to the oxide shell

formed after air exposure of the sample during the deposition of nanoparticles on the carbon foil and the insertion into the electron microscope.

Figure 3. a-c) TEM and b-d) HREM images of Fe NPs obtained in presence of 100 mM of PA and 100mM of HDA after a-b) a 48h aging process under Ar and c-d) after an additional 48h aging under H₂. As inset : corresponding FT pattern confirming the bcc structure observed along [111] and [001] zone axis.

Playing with the ligand concentration, the size of the coalesced particles obtained after 48h of aging under Ar could be tuned between ca. 10 nm (50mM PA/ 100 mM HDA) and 25 nm (100mM PA/ 200mM HDA) (Figure S6). Once more, an additional ageing step under H₂

allowed for the faceting of these particles, leading to nanocubes and nanostars exhibiting {100} facets (Figure S7).

To go beyond morphological observations, a Mössbauer spectroscopy study was performed. Figure 4 shows the evolution of Mössbauer spectroscopy patterns of Fe(0) seeds in presence of 100mM of PA and 100 mM of HDA as a function of the reaction time under either H₂ or Ar atmosphere. The spectra of the raw samples have been collected at low temperature 5K, to limit relaxation phenomena from superparamagnetic small Fe clusters. The analysis of the spectra was done on the basis of our previous Mössbauer investigations, for the seeds only^[35], and for the synthesis of NPs in presence of PA/HDA from the decomposition of {Fe[N(SiMe₃)₂]₂}₂.^[18] Indeed, similar nano-objects and complexes are likely, as similar Fe precursor and ligands are used. All the spectra were then fitted with 4 contributions : Fe seeds^[35], ferromagnetic Fe, an extended phase named as [Fe]_{u-1} in [18], and molecular Fe(II) contributions. [Fe]_{u-1} is not identified, but its high isomeric shift and the large hyperfine field are indicative of the presence of magnetically coupled Fe ions, in an acid environment. The different contributions are detailed in the supplementary information (Table S1, and Figure S8). At room temperature, the Fe(0) seeds quickly evolved, leading to the formation of a molecular complex iron(II) comparable to carboxylate species, as evidenced by the doublet observed at t = 0.^[18] The seed corrosion was however not total, as revealed by the persistence of the seed signature. With time the molecular Fe(II) complex evolved to form the stable [Fe]_{u-1} species. In the following section the Fe(II) reservoir will refer to both Fe(II) molecular and [Fe]_{u-1} species.

Under H₂, metallic Fe(0) species grew significantly but unreacted Fe(0) seeds along with Fe(II) reservoir remained after 48h (Table 1). The time evolution of the reaction was followed by a combined TEM study. Spheres grew homogeneously as revealed by TEM, their size increasing continuously from 2.8 ± 0.2 nm after 30min to 7.1 ± 0.1 nm after 6h, 8.2 ± 0.1 nm

after 12h and 9.9 ± 0.1 nm after 24h (Figure S9). The final size of 10.2 ± 0.1 nm was finally reached after 48h of reaction. Extended further the reaction time did not promote a further decomposition of the Fe(II) reservoir but rather lead to a size broadening. The complete reduction of the Fe(II) reservoir was also not achieved by direct decomposition of $\{\text{Fe}[\text{N}(\text{SiMe}_3)_2]_2\}_2$,^[18] a competition being observed between the Fe(II) species reduction, which induced the liberation of acid species and the further corrosion of Fe(0) seeds.

Under Ar atmosphere, the corrosion of the Fe(0) seeds to give molecular complexes was also evidenced. After 3h, 60% of unreacted seeds still remained, while a small amount of Fe(0) NPs, not detected by Mössbauer were formed as revealed by TEM (Figure S10). Extending the reaction time up to 48h allows the stabilization of a larger proportion of Fe(II) reservoir, resulting from the seeds corrosion. The contribution of the star-like shaped Fe(0) NPs was limited to 16%, revealing that the reaction was far from being complete.

Figure 4. Mössbauer spectra measured at 5K of Fe seeds ripened in presence of 100 mM of PA and 100 mM of HDA at 150°C after different reaction time under Ar or H₂.

Atmosphere	Time	Iron(II)	[Fe] _{u-1} extended phase	Fe seeds	Fe(0) NPs
Ar or H ₂	t ₀	17%	5%	78%	-
Ar	3h	31%	9%	60%	-
	48h	12%	48%	24%	16%
H ₂	30mn	12%	25%	63%	-
	2h	12%	28%	60%	-
	48h	8%	16%	34%	42%

Table1. Evolution of the different contributions deduced from Mössbauer spectra as a function of the reaction duration under Ar or H₂.

Ultrasmall Fe(0) NPs were observed to be reactive at 150°C under H₂ in presence of a mixture of acid/amine ligands. An important proportion was corroded to form a fairly stable iron(II) reservoir which allows for the growth of the remaining unreacted seeds. Ultrasmall Fe(0) seeds acted thus not only as seeds but also as an internal iron source in this new approach. As expected the final size of the objects could be finely tuned by playing with the acid/amine ratio which governs the relative balance between the remaining seeds and the iron(II) reservoir. The higher the acid content, the larger the final NPs due to an extended iron(II) reservoir.

When the aging reaction was performed in presence of Ar atmosphere, the kinetic of both, the seed corrosion and the reduction of the iron(II) reservoir drastically slow down. Few star-like shaped nanoparticles were obtained, probably due to a coalescence process in an amine-rich like environment, as previously invoked for the direct synthesis of Fe NPs.^[18] Thanks to a successive aging step in the presence of H₂, NPs evolved to exhibit mainly (100) facets probably thanks to a growth-reparation mechanism when the acid molecules are slowly retrieved from the iron(II) reservoir, as previously proposed for the direct synthesis of Fe NPs.^[18]

CONCLUSION :

We report here a novel approach for the synthesis of metallic Fe nanoparticles, using ultrasmall NPs as seeds and iron source. In presence of acid/amine environment a complex ripening/coalescence occurs allowing a fine tuning of the final size and shape of the Fe(0) objects obtained. For the first time, star-like shaped Fe NPs exhibiting controlled facets could be reproducibly produced, opening the way for the stabilization of complex 3D magnetic structures. We believe that such simple approach could become a generic method for metallic

NPs synthesis exhibiting complex shapes, indeed, preliminary studies have shown that it can be successfully transposed to Co(0) synthesis.

Experimental section :

Chemicals and Materials.

Due to the air sensitivity of the precursors and nanoparticles obtained, all synthesis were prepared under argon atmosphere by using Fischer-Porter bottles technique, glove box and argon/vacuum lines. Mesitylene (99% Fluka) and toluene (99%, VWR Prolabo), were distilled, degassed and transferred in the glove box prior to use. Hexadecylamine (HDA, 99%) and palmitic acid (PA, 99%) were purchased from Sigma Aldrich and used without any additional purification. The bis(amido)iron dimer $\{\text{Fe}[\text{N}(\text{SiMe}_3)_2]_2\}_2$ (Me = CH₃) was purchased from Nanomeps.

Synthesis of iron (0) nanoparticles

Step 1: Synthesis of preformed Fe(0) seeds.

Preformed Fe(0) seeds were prepared according to a previous procedure.^[29] Briefly, in an Ar glove box, a green solution of $\{\text{Fe}[\text{N}(\text{SiMe}_3)_2]_2\}_2$ (Me = CH₃) (0.5 mmol, 376 mg, corresponding to a Fe concentration of 50 mM) in 20 ml of mesitylene was transferred into a Fischer Porter bottle. The bottle was pressurized with 3 bars of dihydrogen for 10 minutes, and then transferred to a preheated oil bath at 150°C. The solution evolved quickly: after few minutes its color turned to black. The reaction was let to react 24h at 150°C under vigorous magnetic stirring, leading to a 20 mL black solution. After cooling down to room temperature, the reducing atmosphere was removed and the obtained solution was stored in the glove box.

Spherical nanoparticles of 1.5-2.0 nm in diameter homogeneous in size were quantitatively obtained.

Step 2: Ripening in presence of a mixture of ligands.

5mL of the obtained Fe(0) seed solution was used without any further purification and transferred into a Fisher Porter bottle. Palmitic acid (PA) and hexadecylamine (HDA) were added and carefully dissolved thanks to a strong magnetic stirring. The solution was then placed in an oil bath and allowed to react under 3 bars at 150°C for 2 to 7 days.

* Synthesis of 10 nm spherical nanoparticles. Typically 128 mg of PA (0.5 mmol, 100mM) and 121 mg of hexadecylamine (0.5 mmol 100mM) were added to the 5mL seed solution. 10 nm NPs were obtained after 48h of reaction under H₂ at 150°C. Smaller NPs of 7 and 8 nm could be obtained by decreasing the acid content down to 64 mg (0.25 mmol, 50mM) and 96 mg (0.375 mmol, 75 mM) respectively, keeping an amine content of 0.5 mmol (100 mM). The reaction time was extended to 7 days under H₂ to counterbalance the decrease of reactivity observed.

* Synthesis of star-like shaped particles. Typically 128 mg of PA (0.5 mmol, 100mM) and 121 mg of hexadecylamine (0.5 mmol, 100mM) were added to the 5mL seed solution. After 48h of reaction at 150°C under Ar, large coalesced NPs were obtained. The obtained solution was pressurized under 3 bars of H₂ and allowed to react further at 150°C for an additional 48h. Star-like shapes particles exhibiting controlled facets were finally obtained.

Characterization of the NPs.

Microscopy samples were prepared by deposition of a diluted colloidal solution drop on a carbon coated copper grid and observed on a JEOL-1011 for Bright Field Transmission

Electronic Microscopy (TEM) and aberration corrected Tecnai F-20 microscope for High Resolution-TEM (HRTEM) working with 100 kV and 200 kV respectively. In the majority of cases, size histograms were obtained by manual counting process over at least 100 particles, using ImageJ software.^[30] Size distributions have been fitted by Gaussian law; the results are expressed by the calculated mean size and standard deviation σ . Magnetic studies were carried out on powder samples by SQuID (MPMS Quantum Design 5.5) and the iron state and environment were analysed by Mössbauer spectroscopy (WISSEL, ⁵⁷Co source). Samples were prepared into the glove box and extreme care was taken to avoid oxidation during transfer to the apparatus. Microanalysis measurements were performed by ICP (Inductively Coupled Plasma).
