ABSTRACT

Doubly porous polymeric materials were prepared from 2-hydroxyethyl methacrylate (HEMA) through the double porogen templating approach. One such approach required the use of a macroporogenic agent, *i.e.* NaCl particles, and a porogenic solvent. To this purpose, sieved NaCl particles of different size ranges were used (125-200 μm , 200-250 μm and 250-400 μm), either sintered through Spark Plasma Sintering or non-fused, in conjunction with a porogenic solvent, *i.e.* isopropanol. After removal of the, the resulting biporous scaffolds were finely characterized in terms of porosity by scanning electron microscopy (SEM), mercury intrusion porosimetry (MIP), and nitrogen sorption porosimetry. All the obtained results indicated higher porosity ratios and specific surface areas for doubly porous materials prepared from SPS-mediated sintering of macroparticles, thus demonstrating the crucial role of macroporogen packing on the resulting porosity features. Indeed, a higher compaction of NaCl particles generated fewer interstitial voids between adjacent inorganic particles and thus afforded a higher porosity (87 % porosity ratio) in the resulting porous material as compared to the corresponding analogue prepared from non-sintered NaCl particles (80 % porosity ratio). A complementary 3-D imaging of the microstructure by means of X-ray computed microtomography (μCT) but also synchrotron μCT analysis qualitatively confirmed these findings. The macroporogen size was also considered to be a crucial parameter regarding the porosity features, as increasing macroporogen sizes were notably associated with increasing porosity ratios. Finally, swelling of those mono- and biporous materials was investigated. The interconnection in the higher porosity level were notably evaluated and it was observed that the water uptake of biporous PHEMA scaffolds comprising an interconnected higher porosity level can be as high as ~2500%.

Keywords: doubly porous polymeric materials, porogenic agents, Spark Plasma Sintering, X-ray computed microtomography

Introduction

Porous materials with bimodal porosity have been the subject of intense research for many years, mostly because of their large range of applications. They are widely used as innovative materials in many areas, including civil engineering, separative sciences [1-3], tissue engineering [4] and drug delivery applications [5]. In the area of tissue engineering for instance, the first porosity level with pore sizes over 100 μm should allow for efficient seeding and proliferation of suitable cell lines through the material, while the second one with pore sizes lower than 1 μm may permit to improve the nutrient and waste flow within the material when the macropores are clogged at the last stage of the cell culture. In engineering applications, the larger porosity level would allow macromolecules flow through the material, while the smaller porosity level would be dedicated to the passage of smaller molecules or play an important role regarding filtration issues [5-7].

In this context, different strategies have hitherto been developed for the development of polymeric materials exhibiting a double porosity. Temperature-induced phase separation (TIPS) has recently been reported by one of our groups for the design of poly(2-hydroxyethyl methacrylate) (PHEMA)-based scaffolds by using a co-solvent mixture constituted of water and 1,4-dioxane. Solidification process occurred by quenching the PHEMA/co-solvent mixture at a given temperature, and subsequent freeze-drying permitted to obtain biporous PHEMA frameworks [8]. TIPS in conjunction with particle leaching has also been reported earlier for the synthesis of poly(L-lactide)- (PLLA) [9], gelatin- [10] or poly(lactide-*co*-glycolide)- (PLGA) [11] based scaffolds. In these studies, poly(ethyl methacrylate) (PEMA), paraffin, and sucrose spheres (with different diameter ranges) were used as macroporogens, while dioxane, ethanol/water or chloroform allowed for the formation of a lower porosity level during the TIPS process. Furthermore, the High Internal Phase Emulsion (HIPE) technique was also used to obtain PHEMA-based materials with a hierarchical porosity [12-15]. The first porosity level was generated by the removal of an organic porogenic solvent, while the second one resulted from the interconnections between adjacent macropores. The design of doubly porous polymeric materials was also investigated by a double porogen approach involving a macromolecular porogen, *i.e.* poly(ethylene glycol), in combination with NaCl particles to obtain PLLA scaffolds [16]. Finally, in the past few years, doubly porous PHEMA materials were produced *via* a double porogen templating approach through the use of inorganic CaCO_3 [17, 18] and NaCl [19, 20] particles or PMMA beads [17, 18] to generate the macroporosity. The second porosity level was obtained by using either hydroxyapatite nanoparticles [18] or porogenic solvents, such as alcohols [17-19].

In this study, we aim to get a thorough insight into the morphology of model biporous PHEMA-based materials obtained by the double porogen templating approach. In order to generate the macroporosity, either SPS-sintered NaCl particles or non-sintered ones are used as the macroporogenic template, while the second porosity level is generated by using a porogenic solvent through phase separation during the material formation by free-radical copolymerization. We focus our investigation on tuning the macroporosity, and more specifically on the effect of NaCl-template packing and particle size on porosity features associated with biporous frameworks. The porosity of the as-obtained porous materials is carefully characterized by means of mercury intrusion porosimetry (MIP), scanning electron microscopy (SEM), and nitrogen sorption porosimetry. Complementary X-ray computed microtomography (μ CT) and synchrotron μ CT analysis were also performed to investigate the 3-D microstructure and pore morphology of the biporous networks. Finally, swelling behavior of those materials was investigated so as to understand the contribution of each porosity level and the impact of interconnection in the higher porosity level.

Materials and methods

Materials

2-Hydroxyethyl methacrylate (HEMA, 97 %), ethylene glycol dimethacrylate (EGDMA, 98 %), and 2,2-dimethoxy-2-phenylacetophenone (DMPA, 99 %) were purchased from Aldrich. Propan-2-ol (*i*-PrOH, for analysis ACS-Reag. Ph. Eur) was supplied by Carlo Erba. Sodium chloride (NaCl) particles with size ranging from 50 to 500 μ m were purchased from Prolabo; they were then sieved to isolate the particle fractions with sizes ranging from 125 to 200 μ m, from 200 to 250 μ m, and from 250 to 400 μ m that were stored in moisture-free conditions. All reagents and solvents were used without any further purification procedure.

Preparation of doubly porous PHEMA-based materials

Firstly, fractions of 125-200 μ m, 200-250 μ m and 250-400 μ m NaCl particles were fused by Spark Plasma Sintering (SPS) procedure so as to obtain a 3-D NaCl particle template. A Sumitomo Dr. Sinter Lab 515S SPS machine from Fuji Electronic Industrial was used. For the sintering treatment, 2 g of NaCl particles were introduced into a cylindrical graphite die (diameter: 10 mm) and heated from room temperature to 100 °C at a heating rate of 40 °C min⁻¹. A 3 kN force was applied onto the sample under argon. After 5 min at 100 °C, the fused template was cooled to room temperature at a rate of 40 °C min⁻¹. For the sake of comparison, 200-250 μ m sieved NaCl particles were also used without any sintering procedure. 2 g of particles were weighed in a vial and then gently stirred under orbital shaker in order to ensure homogeneous

particle packing. In a second step, HEMA and EGDMA were mixed with a molar ratio of 70/30 mol. % in the presence of DMPA (2 wt. % with respect to the comonomers), and propan-2-ol (80 vol. %). The mixture was added to the NaCl particle template (either sintered or not), and the polymerization was conducted in a UV oven for 4 h at 365 nm. Non-sintered NaCl particles were removed by extraction with deionized water for 3 days (water was changed once a day), while sintered NaCl particles were removed for one day. After this porogen extraction step, the samples were washed abundantly with water, and dried at room temperature under vacuum. The samples were analyzed by gravimetry so as to confirm the total removal of the porogenic agents (NaCl macroparticles and solvent).

Morphology of (bi)porous PHEMA polymers

SEM observation of the materials was performed on a MERLIN microscope from Zeiss equipped with InLens and SE2 detectors using a low accelerating tension (2-3 kV) with a diaphragm aperture of 30 μm . The samples were first cryofractured and coated with a 4 nm layer of palladium/platinum alloy in a Cressington 208 HR sputter-coater.

Determination of porous features

Porosity ratios, pore volumes, and pore size distributions of the materials were determined by mercury intrusion porosimetry (MIP) using a Micromeritics AutoPore IV 9500 porosimeter. The determination of the porosity features was based on the Washburn equation between the applied pressure (from 1.03 to 206.8 MPa) and the pore size into which mercury intruded. The nitrogen sorption measurements were carried out at 77 K with a Quantachrome Autosorb iQ analyzer. The specific surface area values for the investigated porous polymers were quantified using the BET method at relative pressure (P/P_0) values ranging from 0.05 to 0.3.

Study of the microstructure of (bi)porous scaffolds by X-Ray microtomography

The computed X-ray microtomography investigations were performed using an Ultratom microtomograph system manufactured by RX Solutions. Two imaging setups were used, providing 3-D images with different spatial resolutions. In the first one, aimed at imaging the whole manufactured samples of 1 cm in diameter, a Hamamatsu L10801 micro-focus reflection X-ray source (max. 230 kV and 200 W, min. spot size 5 μm) was combined with a Varian 2520 flat panel detector (1920 \times 1536 pixels, pixel size: 127 μm , CSI scintillator). The second configuration based on a Hamamatsu nano-focus transmission L10711-23 source (max. 160 kV and 15 W, min. spot size 0.25 μm) and a 4008 \times 2672 pixels VHR camera from Photonic Science (pixel size 9 μm , Gadox scintillator) was used to investigate smaller samples at a higher resolution. 3-D images were reconstructed from the radiographic projections using the X-act software provided by the manufacturer. For the larger scale investigations, the experimental

protocol consisted in sticking a cylindrical biporous PHEMA sample, about 1 cm in diameter, on top of a thin cylindrical holder, which was mounted on the rotating stage of the microtomograph. The micro-focus source was set at 25 kV tension and 400 μ A intensity, and the geometric setup ensured a voxel size of 8.75 μ m in the reconstructed images. 1440 radiographic projections were taken over a complete 360-degree rotation in about 10 h, and 3-D images of $1840 \times 1840 \times 1270$ voxels were reconstructed. For the smaller scale investigation, the sample of about 3 mm in diameter was held in a plastic straw, which was stuck on the rotating stage. The nano-focus source was used at 50 kV tension and 100 μ A beam intensity. The camera was used in 4×4 binning mode in order to increase the signal to noise ratio. The 700 projections were recorded in about 2 h and the 3-D reconstructed images had a definition of $1000 \times 1000 \times 700$ voxels, with a voxel size of 2.0 μ m; scanning time was about 2 h. All the images shown in this study were analyzed with the Fiji[®] Freeware. As the considered materials were almost transparent to X-rays, the obtained images were rather noisy. That is the reason why they had to be digitally filtered for some investigations; the “2-D anisotropic diffusion” filter available in Fiji has been selected to process the 2-D slices, for its ability to reduce noise while preserving interfaces.

Synchrotron X-ray tomography imaging

The synchrotron X-ray tomography investigations were performed at Synchrotron Soleil (Saint Aubin, France) on the ANATOMIX beamline with a parallel beam and a pink beam with an energy range from 5 to 25 keV, resulting from the use of a 12.5 mm gap on the undulator and filtering by Au. Note that the Anatomix beamline is the latest beamline of Synchrotron, constructed in the context of the EquipEx project NanoImagesX. Our experiment run in April 2018 was the first official user-experiment on this line, which was still in a temporary, not optimized, configuration. A local tomography was performed with a $10 \times$ optics in absorption contrast mode and a Hamamatsu Orca Flash 4.0 V2 camera (2048×2048 pixels, 6.5 μ m), associated with a scintillator 500 μ m in thickness. The cylindrical material of about 1 cm in diameter was stuck on a PMMA sample holder inserted on the rotating stage. Radiographic scans using 2000 to 8000 projections were run together with the acquisition of "dark" (*i.e.* without beam) and "at" images (*i.e.* without sample), averaged over 50 frames. Because the setup was not yet optimized, only the central part of the radiographs were perfectly focused, on a height of about 1000 pixels. During these experiments, 2 acquisition modes were carried out. In the first one, the sample is scanned over 180° (4 times) to reconstruct an image of 2000×2000 pixels with low noise. The second one is a 360° scan with an off-center axis and 2 heights, to reconstruct 2 juxtaposed images of $4000 \times 4000 \times 2000$ pixels with an overlap.

Water uptake determination

In a typical experiment, a known weight (W_d) of PHEMA (bi)porous polymer was immersed in milliQ deionized water. At specific times, the same sample was weighted to obtain W_w as a function of time. The water uptake of the polymer networks can be expressed following **Eq. (1)**:

$$\text{Water Uptake} = \frac{W_w - W_d}{W_d} \quad \text{Equation 1}$$

where W_w and W_d stand for the wet mass and the dry mass, respectively. The monitoring of water uptake as a function of time was stopped when a plateau was reached.

Results and discussion

As previously demonstrated in different studies, NaCl particles have been successfully used to generate macroporous [21] or biporous materials through particle templating combined to a porogenic solvent after a straightforward porogen removal [22-24]. It should be stressed that previous reports based on the double porogen approach using NaCl as a macroporogen only concerned either non-sintered NaCl particles [16] or sintered ones [23, 24], and no thorough investigation of the influence of nanoporogen or even macroporogen features on pore morphology was provided. Recently, we have developed a somehow smarter strategy toward doubly porous PHEMA-based networks in which NaCl macroparticles sintered through the SPS technique are used to form a 3-D continuous macroporogenic template in conjunction with a porogenic agent consisting of a suitable solvent. In one such case, the 3-D continuous NaCl particle-based template leads to a macroporosity level, while the porogenic solvent ensures a lower porosity level through a phase separation process during the polymerization step [18-20]. At this stage, it is worth mentioning that the porogenic solvent must obviously be miscible with the comonomers in order for the phase separation to occur during the copolymerization process. Indeed, when the polymerization is at an advanced step, the incompatibility between the solvent and the polymeric network results in the expulsion of solvent molecules from the polymer, thus leading to pores whose sizes depend notably on the nature and concentration of the solvent as well as the crosslinker concentration [19]. The advantage of our approach, that is based on the concomitant use of two distinct porogenic agents, namely NaCl macroparticles and a porogenic solvent (*i*-PrOH in the present study), lies in the independent control of each porosity level. In

our previous studies [19], we have thus shown that the use of more and more hydrophobic alcohols as porogens for the preparation of hydrophilic PHEMA-based crosslinked materials leads to increasing average pore sizes for the lower porosity level without any significant modification of the macroporosity. Likewise, an increasing proportion of the porogenic solvent also leads to increasing pore sizes related to the lower porosity level, while decreasing the upper to lower porosity ratio.

Effect of macroporogen packing on doubly porous materials

The present study is specifically focused on the macroporogen packing effect on biporous PHEMA-based networks by comparing sintered *vs.* non-sintered NaCl macroparticles with a size range comprised between 200 and 250 μm . The polymerization mixture was constituted of a fixed HEMA/EGDMA molar ratio of 70/30 mol. % in conjunction with 80 vol. % *i*-PrOH with respect to the comonomer volume. The MIP profiles and SEM micrographs of the resulting doubly porous PHEMA-based materials are respectively reported in **Fig. 1** and **Fig. 2**, while their main porous features are gathered in **Table 1**. The biporous structure prepared from non-sintered NaCl particles (**Fig. 1a**) exhibited an ill-defined dual porosity along with pore sizes with a macroporosity centered around 200 μm and a lower porosity level centered around 6 μm . In sharp contrast, doubly porous networks prepared from SPS-sintered NaCl particles presented a well-defined bimodal porosity with a first macropore size of about 60 μm and a second macropore size around 1.5 μm , as observed in **Fig. 1b**.

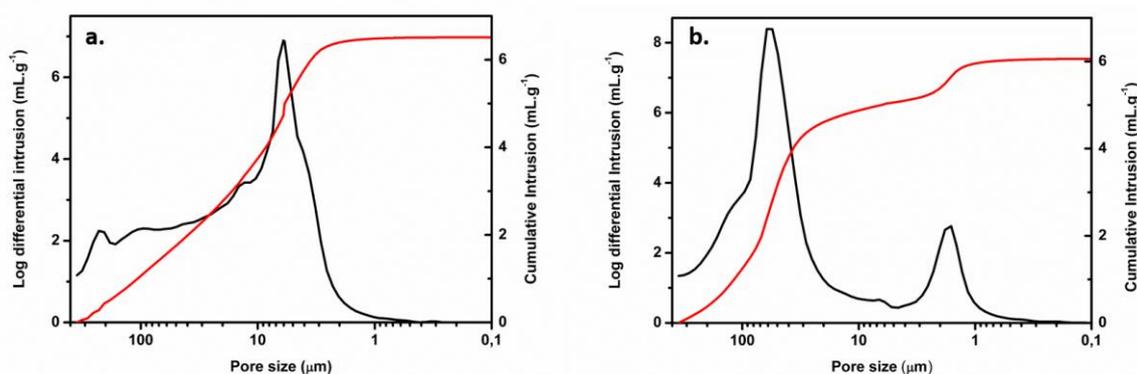

Fig. 1 MIP profiles of biporous PHEMA materials prepared from 200-250 μm non-sintered (a) or SPS-sintered (b) NaCl particles.

Table 1 Porous features of biporous PHEMA-based materials with non-interconnected and interconnected macropores.

Porous characteristics	Non-interconnected macropores	Interconnected macropores
Larger macropore size (μm) ^a	200	60
Smaller macropore size (μm) ^a	6	1.5
Upper to lower porosity ratio (vol. %) ^a	nd ^c	80/20
Total pore volume (mL g^{-1}) ^a	6.5	6.0
Porosity ratio (%) ^a	80	87
Specific surface area ($\text{m}^2 \text{g}^{-1}$) ^b	80	105

^a Values as determined by MIP.

^b Values as determined by nitrogen sorption measurements (BET method).

^c This ratio could not be determined properly.

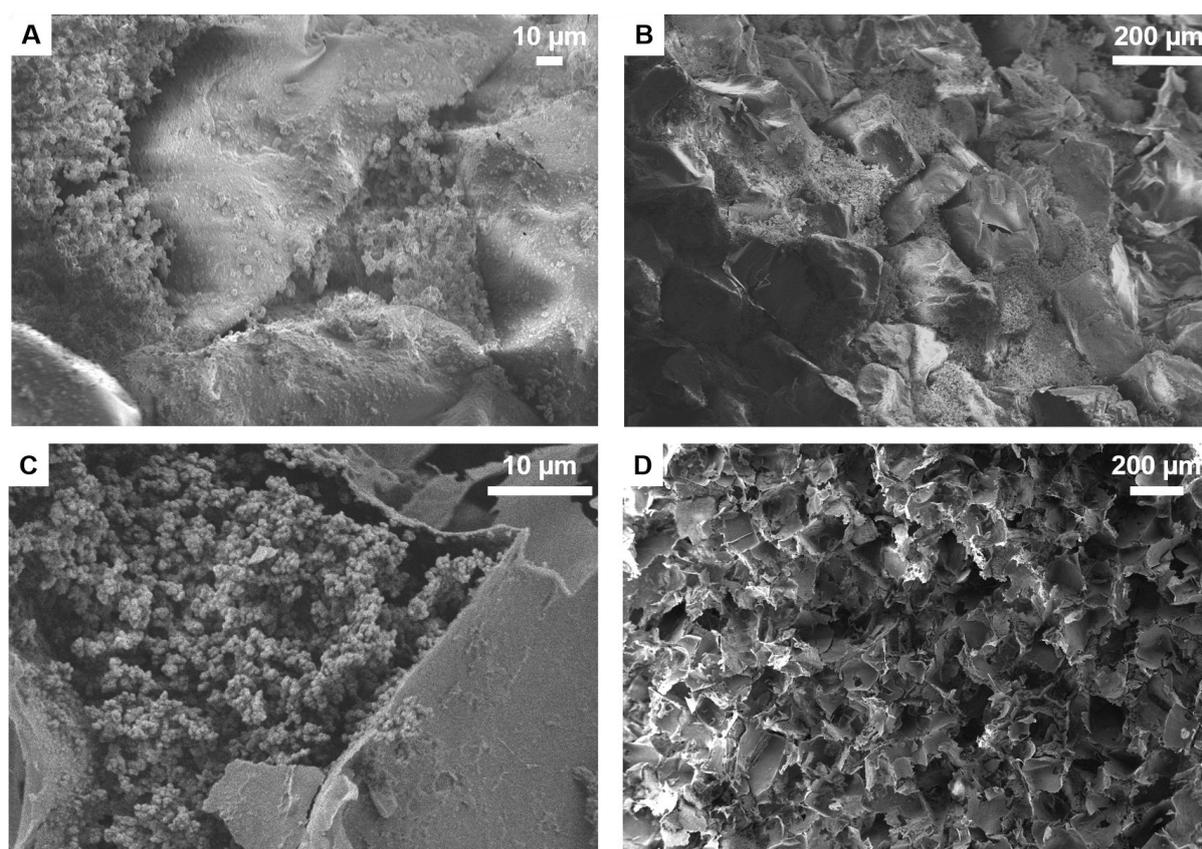

Fig. 2 SEM micrographs of biporous PHEMA-based materials with non-interconnected macropores prepared by using non-sintered NaCl particles (A,B) and with interconnected macropores prepared by using SPS-sintered NaCl particles (C,D).

It is worth mentioning that the pore sizes obtained from MIP measurements are often underestimated when compared to SEM observations. This has already been observed notably with poly(HIPE) samples [25] or when using fused PMMA beads as macroporogens [20], and it could be explained by the threshold size theory that was reported in the literature concerning MIP measurements on cement-based materials [26]. This original biporous material presented an upper to lower porosity volume ratio equal to 80/20 vol. %. In this case, the resulting biporous material presented interconnected macropores and thus a higher porosity ratio, *i.e.* 87 % compared to 80 % for the corresponding analogue prepared from non-sintered NaCl particles, due to closer particle packing resulting from SPS-mediated NaCl sintering. As it can be seen in **Fig. 2**, SEM observations of the biporous material prepared from non-sintered macroporogenic agent clearly showed the occurrence of two porosity levels. Non-interconnected macropores having NaCl particle imprints could be detected (**Fig. 2B**), while globular polymeric structures were observed within the macropore walls delimiting an interconnected network with a lower porosity level (**Fig. 2A**), that is usually found when phase separation occurs in such polymerization mixtures constituted of at least one porogenic solvent. In the latter case, the interconnection between adjacent macropores appeared to be largely absent. Comparatively, SEM investigation of the biporous PHEMA framework obtained from sintered NaCl particles showed a high level of interconnections between adjacent macropores, while each level of porosity was preserved. One such sample exhibited a higher specific surface area, *i.e.* $S_{\text{BET}} = 105 \text{ m}^2 \text{ g}^{-1}$, than that with non-interconnected macropores ($S_{\text{BET}} = 80 \text{ m}^2 \text{ g}^{-1}$), as measured from nitrogen sorption porosimetry.

μCT has recently been implemented for the characterization of macroporous polymer-based materials, and especially for biodegradable porous polymers dedicated to tissue engineering applications [27-32]. This remarkable technique notably allowed for some 3-D volumic rendering of the porous materials or the corresponding macroporogenic templates [30], thus leading to significant information that could be complementary to more classical SEM and MIP techniques. A significant advantage of μCT with respect to SEM was its ability to investigate the bulk of the material in a non-destructive manner, with almost no constraints in terms of sample preparation. Unlike MIP, it provided also a direct, at least qualitative, information on pore size and geometry. On the other hand, spatial resolution of μCT was still limited and the low X-ray absorption contrast provided by highly porous polymeric materials led to noisy images.

μCT imaging was first performed on doubly porous PHEMA cylindrical samples 1 cm in diameter, and in this particular case, the NaCl macroporogens were not previously sieved (grain

size between 50 and 500 μm). The microstructure of samples elaborated from non-sintered (**Fig. 3a**) and SPS-sintered (**Fig. 3b**) NaCl particles permitted to confirm the surface observations made by SEM regarding the macroporous network (*i.e.* upper porosity level). As shown in **Fig. 3**, the pore distribution was rather homogeneous in both samples, and they showed a macroporous network with pore imprints of sizes similar to those of NaCl particles. The exploration of the 3-D image of the sample prepared from non-sintered NaCl (cross-section presented in **Fig. 3a**) qualitatively confirmed that the macropores were mostly isolated within the polymer matrix. The macropore morphology presented various shapes, such as pseudo-cubes, spheres, and pyramids. The matrix exhibited some large areas without pores, a few hundred micrometers in size; some thin matrix walls separating pores, or even inside pores, with a thickness close to voxel size, could however also be observed. A few neighbor pores seemed to be connected; it was however not clear whether they were separated or not by a thin matrix wall which could not be resolved by the 3-D image of the whole samples. Such situations were however seldom.

The 3-D μCT image of the sample obtained from the SPS-fused particles, a cross-section of which was provided in **Fig. 3b**, showed a microstructure with mostly pseudo-spherical pores separated by much regular and thinner matrix walls (less than 50 μm). However, the 3-D exploration of these data showed that most pores seemed to be connected to their neighbors. Similar connections could be found for almost all pores in other cross-sections. Strictly speaking, this did not prove that pores were really connected, as separating walls could have been too thin with respect to image resolution. These observations were however consistent with the expected features of the microstructure of this material. It is noteworthy that some bright area could be observed on the periphery of the sample reflecting strongly attenuating constituents, which might be residual NaCl particles potentially entrapped in the material and not removed during preparation.

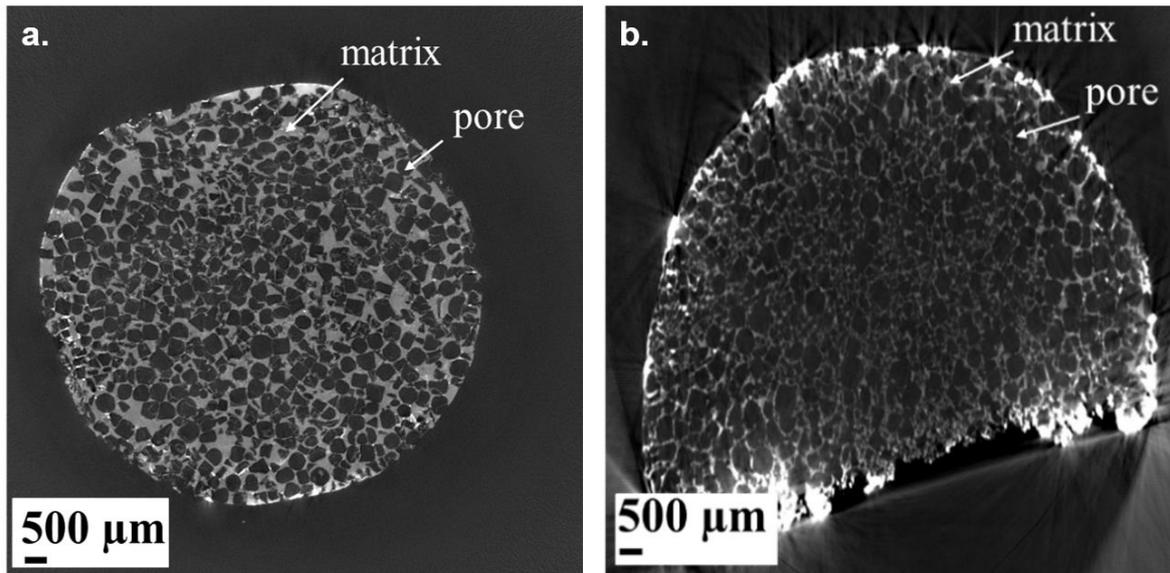

Fig. 3 μ CT pictures of porous PHEMA-based networks exhibiting non-interconnected macropores (a) and interconnected macropores (b).

The major differences between both samples, as qualitatively demonstrated by the μ Ct images, laid in the interconnection between adjacent macropores, the pore shape and the matrix volume fraction. It is noteworthy that the polymer matrix proportion was obviously more important for the material displaying non-interconnected macropores. This could be explained as the consequence of the random packing of inorganic macroporogens used in the preparation of the NaCl template associated with the porous materials. This result was also confirmed more quantitatively by experimental measurements of the density of samples elaborated from non-sintered NaCl particles which was equal to 0.093 g.cm^{-3} while materials prepared with SPS-sintered NaCl particles showed a 0.067 g.cm^{-3} density. Such a global measurement of density allows one to directly compare the macroporosity, if one assumes the lower porosity level to be the same in both samples, which sounds reasonable in a first approximation as both pore forming mechanisms are essentially independent.

Furthermore, the macroporosity of the sample obtained from non-sintered NaCl was quantitatively evaluated from its μ CT image with the following methodology. The average grey level g_{av} of a large region of interest of the sample, made of 200 slices, was compared to the average grey level of voids g_v , and of microporous matrix g_m , which could be determined by a manual selection within a 2-D cross section of sufficiently large domains strictly included in the pore or matrix phase. As grey levels in μ CT images reflect average X-ray attenuation coefficients, which in case of two-phase materials are essentially proportional to the volume

fraction of constituents within voxels, a simple rule of mixture can be used to evaluate the average macroporosity P from these quantities,[33] according to $g_{av} = P \times g_v + (1-P) \times g_m$. When applied to non-filtered images (see **Fig 4a** for a typical cross- section), this procedure led to an evaluation of P of 64 %.

A similar procedure could however not be applied efficiently to the other sample obtained from fused NaCl because the value of g_m was difficult to quantify precisely, for two reasons (see **Fig. 4d**): first, the matrix domains are much thinner so that it is hard to select large domains made of matrix only, and second, the grey levels within the matrix exhibited larger fluctuations, possibly because of a larger variability of the lower porosity level, or the presence of residual traces of NaCl (as observed near the periphery of the sample). However, assuming a similar lower porosity level in both samples, the macroporosity of the second material could be deduced from that of the first one and from the ratios of the overall densities. In this way, a macroporosity of 74 % was found for SPS-sintered samples, *i.e.* a value very close to that found independently by means of MIP, which is $0.8 \times 0.87 = 70$ %.

Let us finally stress that a more conventional approach to evaluate volume fractions would have been based on a segmentation of images. It would however have been much less accurate and possibly biased, because of the high noise level of the images and the voxel size which is too large with respect to many small features of the microstructure, such as wall thicknesses. To illustrate this, a filtered region of interest made of 200 slices (see **Fig. 4b** for a representation of one of these) has been segmented making use of a threshold chosen such that the pore phase, defined as the voxels with a grey level below this value, represent 64 % of all voxels. The resulting image is illustrated in **Fig. 4c** which shows significant differences with **Fig. 4a**, especially regarding the polymer walls. This holds for images of the material obtained from non-sintered NaCl grains; the situation is even more critical for the other one, for which conventional thresholding would lead to meaningless results.

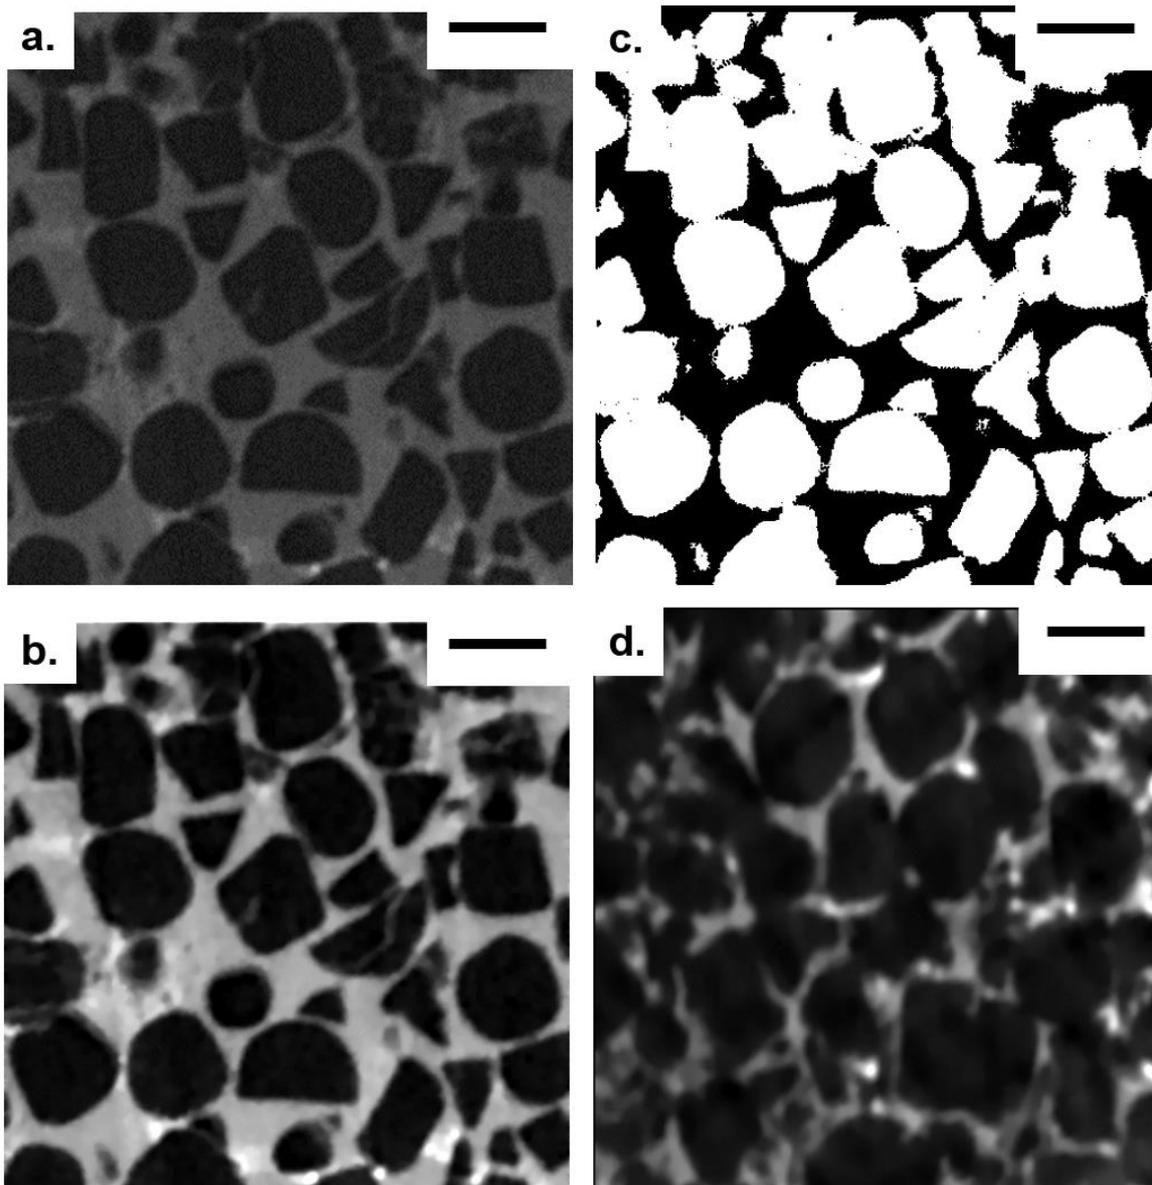

Fig. 4 μ CT enlarged pictures of porous PHEMA-based frameworks: (i) exhibiting non interconnected macropores before (a) and after image processing (b) as well as corresponding area after segmentation (c) or (ii) exhibiting interconnected macropores (d). Scale bars represent 500 μ m.

Effect of macroporogen size on doubly porous materials

Further, the macroporosity of biporous PHEMA-based samples was carefully investigated by varying the size of NaCl particles used to generate the 3-D inorganic template of the porous materials. The choice of the macroporogen size had no significant influence on the lower porosity level as the two pore-forming mechanisms are independent, as mentioned above. The amount of porogenic solvent was kept constant, while three different fractions of sieved NaCl

particles, *i.e.* 125-200 μm , 200-250 μm , and 250-400 μm , were used to prepare biporous PHEMA-based materials that were then characterized finely in terms of porosity features. MIP profiles reported in **Fig. 5** logically showed a correlation between an increase in the macroporogen size and an increase in the size of resulting macropores and pore volumes. For the lowest NaCl size (*i.e.*, 125-200 μm), a macroporosity centered on 40 μm was observed with a 77 % porosity ratio. For the intermediate particle size (*i.e.*, 200-250 μm), the macropore size was nearly centered on 60 μm with an 87 % porosity ratio. Finally, biporous materials designed with the highest macroporogen size (*i.e.*, 250-400 μm) exhibited a macropore size of about 70 μm and a porosity ratio equal to 88 %. Again, it is noteworthy that the macroporogen size was higher than the corresponding macropore size. This is actually quite often observed with porous materials for which the pore size determined by MIP is generally underestimated when compared to SEM observation, likely due to the threshold size theory [25, 26]. Likewise, specific surface area values increased gradually with increasing macroporogen sizes, while the upper to lower porosity volume ratio was nearly constant (**Table 2**).

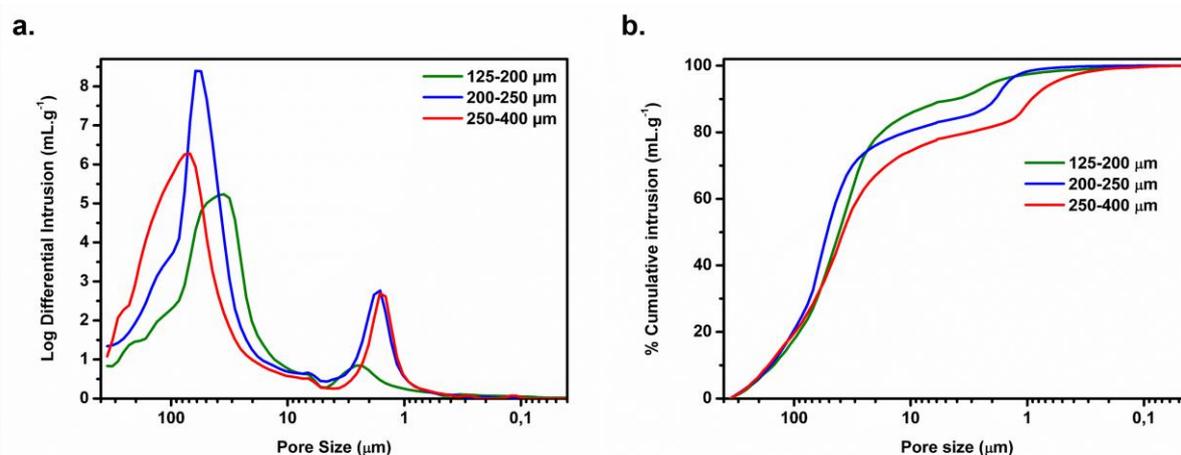

Fig. 5 (a) MIP pore size distribution profiles and (b) cumulative intrusion volumes of biporous PHEMA-based materials prepared from sintered NaCl particles in the presence of *i*-PrOH as a porogenic solvent. Three NaCl particle size fractions were used, *i.e.* 125-200 μm , 200-250 μm , and 250-400 μm .

Table 2 Porous features of biporous PHEMA-based materials with varying interconnected macropore sizes.

NaCl size (μm)	Larger macropore size ^a (μm)	Smaller nanopore size ^a (μm)	Upper to lower porosity ratio ^a (vol. %)	Total pore volume ^a (mL g^{-1})	Porosity ratio ^a (%)	Specific surface area ^b ($\text{m}^2 \text{g}^{-1}$)
125-200	40	2.3	83/17	4.5	77	95
200-250	60	1.5	80/20	6.0	87	105
250-400	70	1.4	77/23	10.7	88	177

^a Values as determined by MIP

^b Values as determined by nitrogen sorption measurements (BET method)

Biporous networks prepared from 125-200 μm and 200-250 μm NaCl particles were analyzed *via* μCT imaging. As shown in **Fig. 6** and **Fig. 7**, the macropore dispersion was homogeneous for both samples but some areas showed larger pores (approximate diameter: 500 μm) due to NaCl particles aggregation during sintering step. For both samples, porosity ratio was again difficult to estimate accurately using either of the above presented methods, because of high noise levels, low contrast difference between the polymer matrix and voids, and too coarse voxel size with respect to microstructural features.

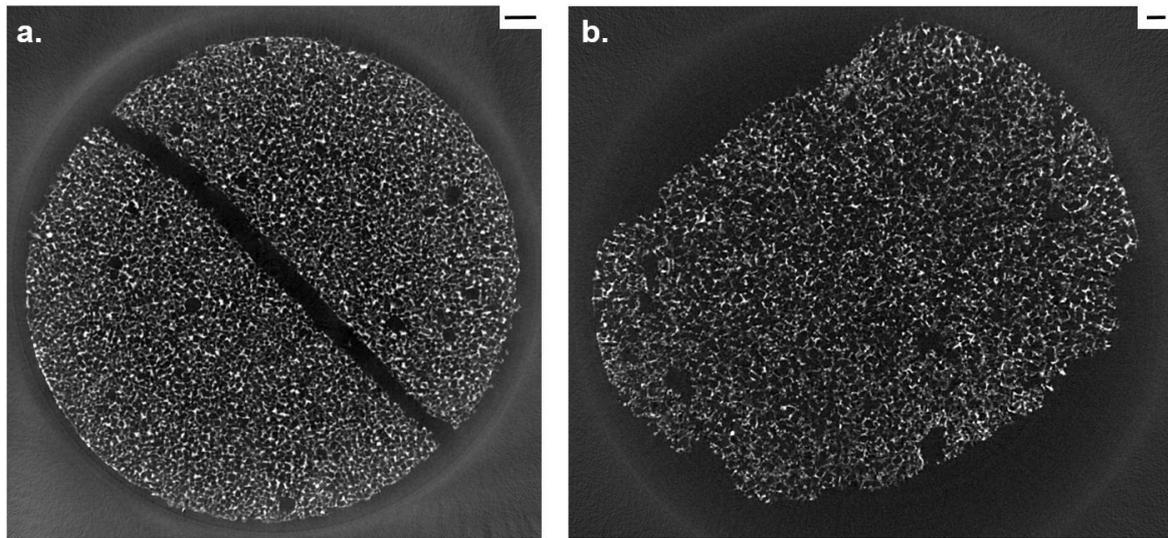

Fig. 6 μCT pictures of biporous PHEMA-based networks prepared from 125-200 μm (a) and 200-250 μm (b) NaCl particles. Scale bars represent 500 μm .

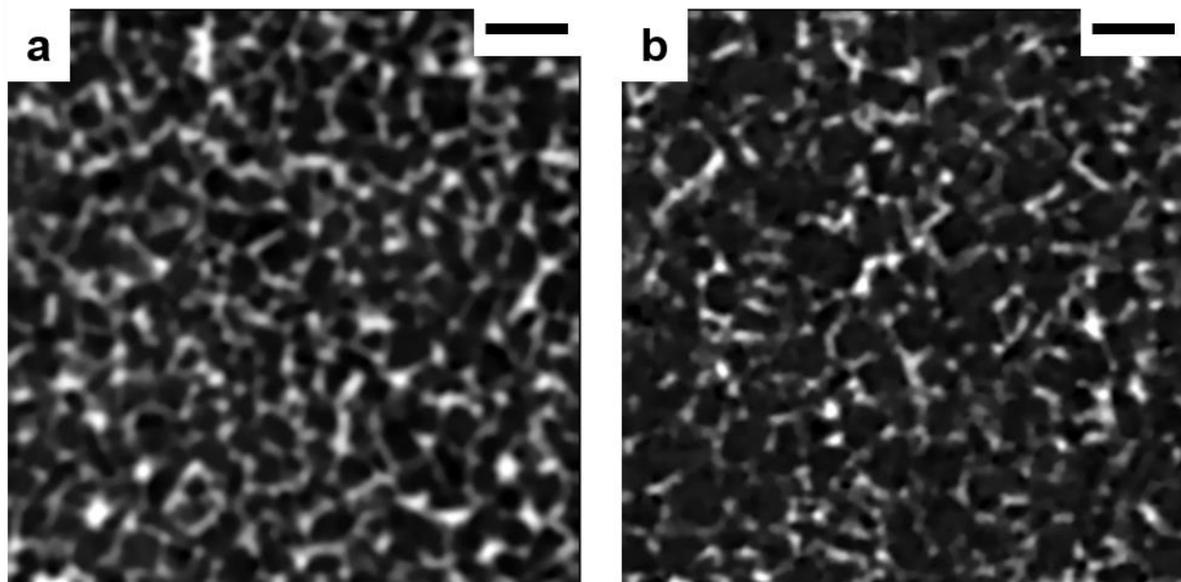

Fig. 7 μ CT enlarged pictures of porous PHEMA-based frameworks exhibiting interconnected macropores generated from 125-200 μm (a) and 200-250 μm (b) NaCl particles. Scale bars represent 500 μm .

In order to investigate more precisely the morphology of these materials, a sample prepared with 200-250 μm sintered NaCl particles was observed *via* μ CT measurements with higher spatial resolution, namely a voxel size of 2.0 μm instead of 8.75 μm . Despite the noise, **Fig. 8** permitted to clearly observe a porous network (corresponding to the lower porosity level) within larger matrix domains, surrounded by uniform thin walls. This thickness of the latter was about 1 voxel in the images, indicating an actual physical width lower than the voxel size. This result was in good agreement with the previous SEM micrographs showing a porous structure surrounded by a homogenous polymeric shell. Furthermore, μ CT image showed some isolated matrix filaments certainly formed in the thin areas near the necks between sintered grains, or in the cracks in the NaCl particles caused by the SPS sintering step. This very fine structure could not be resolved accurately within the images with a coarser voxel size, which explained the difficulty to segment the latter. Because of very high noise levels, it was also difficult to segment efficiently the higher resolution images. Further 3-D imaging attempts using devices with higher photon fluxes as those available on synchrotron facilities are planned in forthcoming work to investigate more quantitatively the microstructure of such materials.

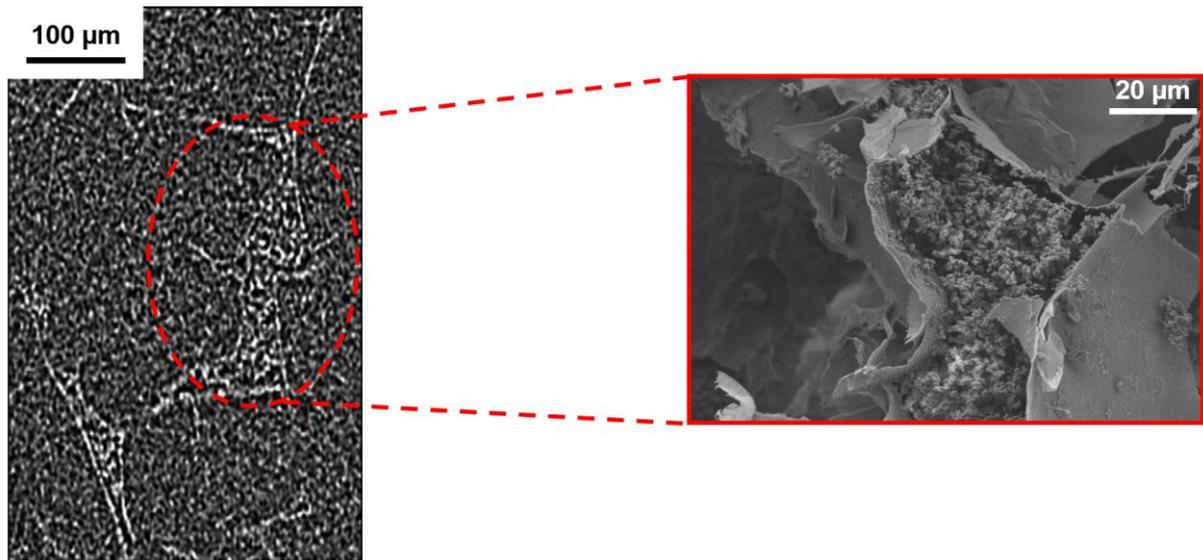

Fig. 8 μ CT picture and SEM micrograph of porous PHEMA-based framework exhibiting interconnected macropores generated from 200-250 μ m NaCl particles.

The use of synchrotron radiation as an X-ray source brought important improvements to the imaging. [34, 35] Synchrotron radiation results from the bending of a higher energy electron beam due to a magnetic field. The main advantage of this technique is that the high flux allows one to resolve very subtle variations in absorptivity and therefore in internal structure. Additional advantages of synchrotron radiation include X-ray beam collimation, which simplifies the tomographic reconstruction algorithm, and the tunability of the X-ray energy to a narrow energy band. Moreover, the use of a monochromatic X-ray beam improves the accuracy of the reconstructed tomographic images by eliminating the issue of energy dependence on X-ray absorption. In our case, synchrotron imaging is expected to provide much more accurate, less ambiguous, more spatially resolved and much less noisy images, within more reasonable scanning times. It is important to mention that the experiments were carried out on a new and not yet optimized beamline (Anatomix, Synchrotron Soleil, Saint-Aubin, France) that did not yet include a monochromator. The experiments were therefore carried out using a wide X-ray spectrum determined by the gap of the magnets and a solid filter. The spectrum was thus reduced to approximately 10 keV providing more suitable radiation for polymer absorption compared to laboratory microtomography. Moreover, all the samples were observed directly after the elaboration without the incorporation of a contrast agent. The observation was performed on biporous samples prepared from sintered and non-sintered NaCl particles with sizes ranging from 125 to 400 μ m (**Fig. 9**). Monoporous materials with large interconnected and non-interconnected pores (200-250 μ m) were also analyzed in a second step

(Fig. 10). X-ray synchrotron tomography permitted to considerably reduce the noise and the ring artifacts without image processing tools such as 2-D anisotropic filter. Moreover, the main advantage is that the use of a contrast agent was not necessary because the beam energy and the spatial resolution were more adapted. The reconstructed volumes were higher (2000^3 pixels and 4000^3 pixels vs. 1700^3 pixels for classical microtomography) as well as the number of radiographic projections ($4000/8000$ vs. 1440). This technique permitted also to reduce the scanning time from 9 h to few minutes. As observed in the **Fig. 9**, the conclusions that have been made for the images obtained with classical X-ray tomography are confirmed. Indeed, three different features could be observed: the large pores, the porous polymeric matrix and the thin polymeric walls. We could notice that the interconnected materials prepared with the lowest NaCl particles size (*i.e.* 125-200 μm) exhibited less polymeric matrix. Indeed, as the grains were smaller, these templates would have required more reactants (monomers) to form a sufficient amount of polymer which could fill all the template interstices. Furthermore, the omnipresence of the walls deformation probably induced by the drying is even more visible particularly for non-interconnected networks regardless the salt size used during the elaboration. Such observations also permitted to confirm the reliability of the use of Lugol solution, as the microstructures features are similar with and without contrast agent.

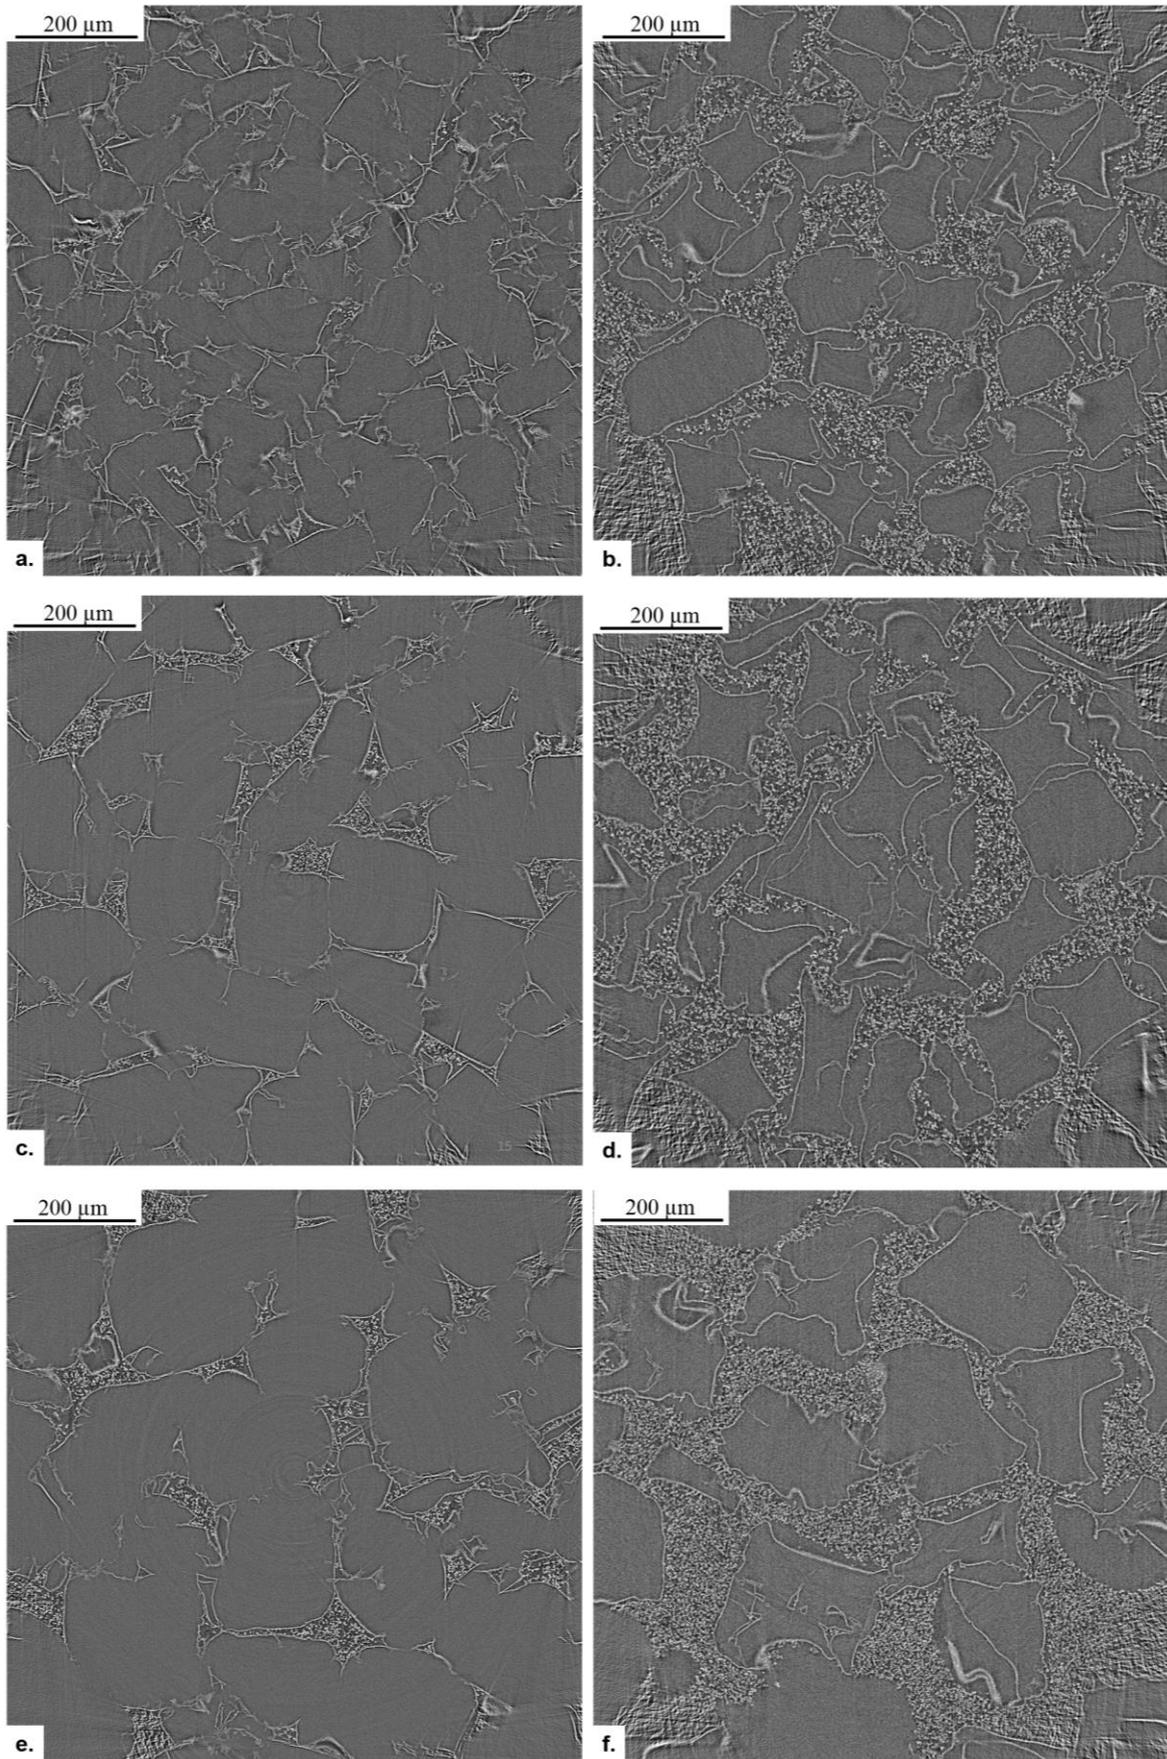

Fig. 9 Synchrotron images of doubly porous networks prepared with 125-200 μm sintered (a) and non-sintered NaCl particles (b), prepared with 200-250 μm sintered (c) and non-sintered

NaCl particles (d) and prepared with 250-400 μm sintered (e) and non-sintered NaCl particles (f).

The materials exhibiting only large pores were elaborated without the use of propan-2-ol as porogenic solvent. In **Fig. 10a** corresponding to an interconnected network with large pores, the non-porous polymeric matrix could be observed, and the large pores size was similar to the one obtained with biporous materials (**Fig. 9**). In the material exhibiting non-interconnected large pores (**Fig. 10b**), we could observe that the NaCl particles were not completely extracted from the material. This is probably due to the resin that has been formed during the polymerization.

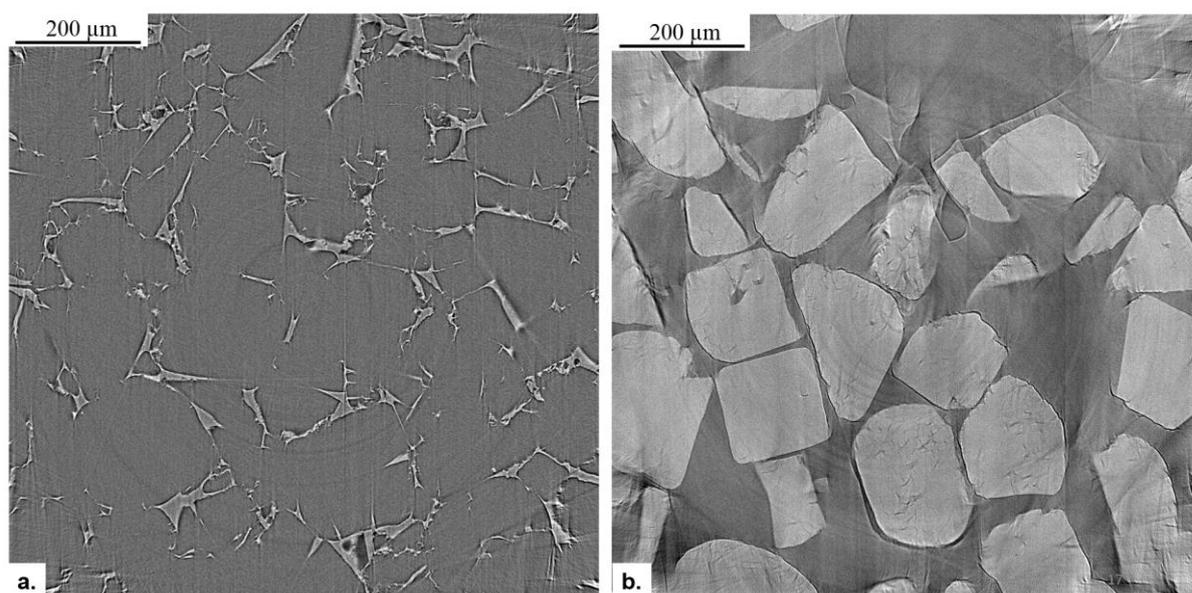

Fig. 10 Synchrotron images of monoporous networks prepared with 200-250 μm sintered (a) and non-sintered NaCl particles (b).

Swelling properties of mono- and biporous PHEMA-based materials

Some of us recently demonstrated that the presence of distinct (non-)interconnected porosity levels within biporous polymeric scaffold has a crucial impact on their fluid flow transfer properties, especially on imbibition and drying. [36, 37] Several studies have also been performed regarding the swelling behavior of PHEMA-based materials in the presence of water. [38-40] For PHEMA-based biporous networks, it has been evaluated by measuring the evolution of the water uptake during 4 h. Previously, Mabilleanu *et al.* have notably highlighted the effect of the crosslinker backbone length on bulk PHEMA water uptake and thus swelling. [38] PHEMA crosslinked with polyethylene diacrylate exhibited the highest value of water uptake, *i.e.* 56 %, while the lowest values were obtained for divinylbenzene-crosslinked

PHEMA and EGDMA-crosslinked PHEMA (40 % and 42 %, respectively). The study was performed on interconnected and non-interconnected biporous networks prepared from NaCl particle size between 200 and 250 μm . **Fig. 11** represents the water uptake of interconnected and non-interconnected biporous networks as a function of time. In both cases, two plateaux were observed that probably correspond to the water filling of each porosity level. Indeed, it is likely to happen that water enters the large and small pores before binding with the polymer. In the case of interconnected networks, the water filling began with the channels between larger pores and then larger pores during 20 min. Then, the water uptake reached a constant value equal to 1500 % during 30 min. In a second step, water drains for 1 h through smaller pores before reaching a second plateau. At the end of the experiment, the water uptake was approximately equal to 2400 %, and the mass of the wet material was almost 24 times higher than that of the dry sample. In the case of non-interconnected networks, the evolution of the swelling degree was similar excepted for the second plateau which was reached less rapidly than in the case of interconnected networks (180 min vs. 120 min, respectively). This difference is likely due to the lack of interconnections between larger pores which should facilitate the draining of water. The water uptake was then lower in the case of non-interconnected biporous networks. Indeed, the material incorporated 1200 % of water at the end of the experiment.

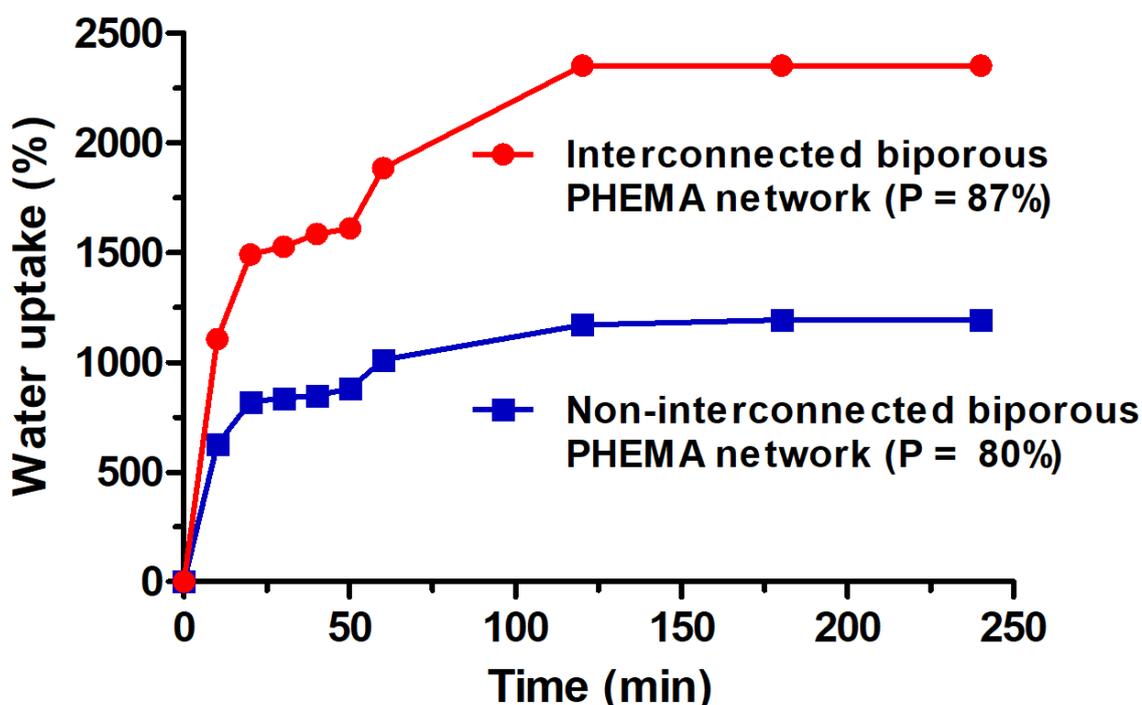

Fig. 11 Water uptake of non-interconnected and interconnected biporous networks as a function of time (*P = porosity ratio).

Water uptake was also evaluated with monoporous PHEMA-based polymers. Some previous studies showed that a bulk PHEMA-based polymer (HEMA/EGDMA, 96/4 mol. %) incorporated 58 % of water after 2 days. [38] Moreover, Lokman *et. al* found that PHEMA porous monoliths crosslinked with maleic anhydride and presenting 78 % porosity were able to incorporate 68 % of water. [40] Finally, Gomes *et. al* showed that the water uptake of scaffolds prepared with ethylene vinyl alcohol and cellulose acetate could reach values of around 30 %. [41] For the sake of comparison, we performed this study on monoporous materials exhibiting large pores or small pores. The swelling degree as a function of time is reported in **Fig. 12**. As expected, a monoporous network incorporated less water than a biporous one. We could notice that the equilibrium swelling degree was reached after 10 min in the case of a material with small pores (350 % water uptake), 40 min for a material with large interconnected pores (275 % water uptake) and 180 minutes for large non-interconnected pores (50 % water uptake). It is important to mention the presence of one single plateau in the case of monoporous samples. This observation permitted to confirm the hypothesis in which the two porosity levels were filled gradually in the case of biporous networks. In the case of materials exhibiting only small pores and samples exhibiting interconnected large pores, a constant swelling degree was reached rapidly, whereas water had more difficulties to drain through the materials with non-interconnected large pores. We could explain this phenomenon by the lack of interconnections between the larger pores. Moreover, the absence of smaller pores reduced the path of the fluid through the material. Furthermore, the thin resin formed around the material during the polymerization (due to the absence of porogenic solvent) could also slow down the passage of water. As expected, the lowest swelling degree was obtained in the case of non-interconnected monoporous network with only 50% water uptake. This observation permits to explain the low permeability of these materials and their low water uptake compared to the other structures. Finally, as expected, the swelling ratio of bulk PHEMA is very low, i.e. 6%, when compared to its (bi)porous counterparts.

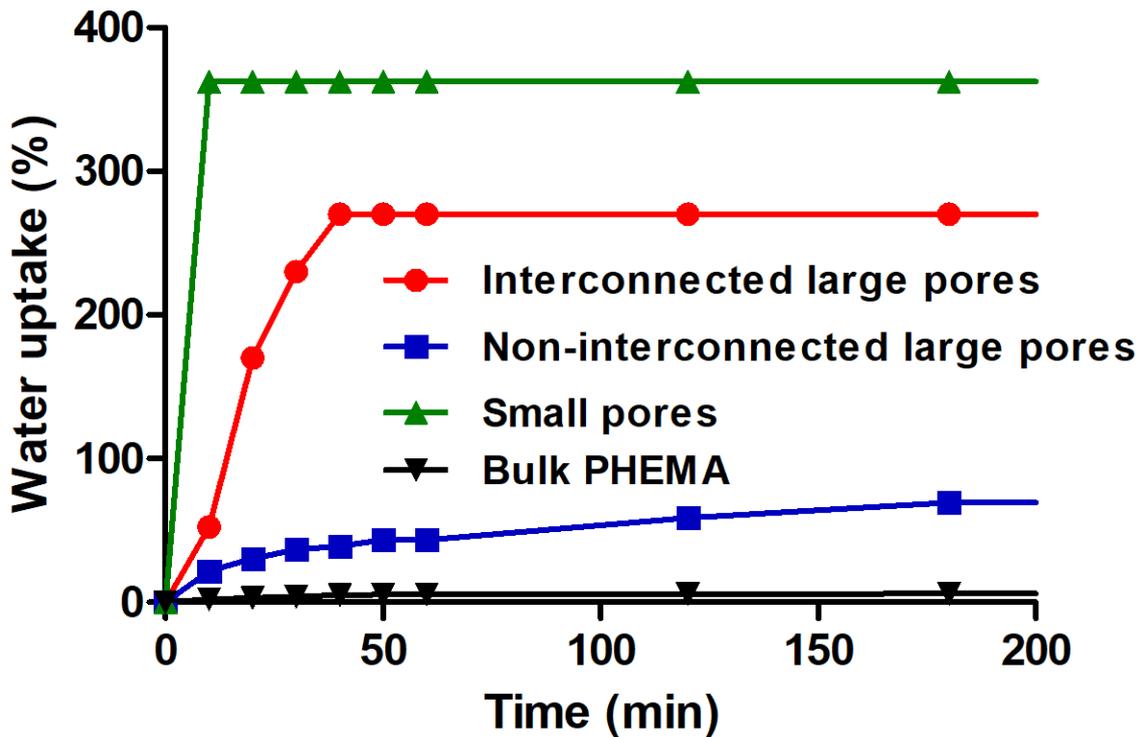

Fig. 12 Water uptake of monoporous networks with interconnected and non-interconnected large pores and small pores as a function of time (*P = porosity ratio).

Conclusions

This paper demonstrated the pivotal role of porogenic particle packing on the pore interconnectivity in biporous PHEMA-based materials obtained through the double porogen templating approach. SPS-mediated macroporogen sintering induced a higher compaction of NaCl particles, thus generating fewer interparticular voids, and eventually afforded a higher porosity ratio of the resulting porous polymeric materials with interconnected macropores. The NaCl macroporogen size was also determined to be a crucial parameter regarding the porosity features, as increasing macroporogen sizes were associated with increasing porosity ratios. A X-ray computed microtomography (μ CT) analysis confirmed these results as the 3-D microstructure observed in the case of the material prepared from non-sintered NaCl particles pointed out some sparse interconnections between adjacent macropores, likely due to very few contact points between neighbor NaCl particles in the 3-D inorganic template of the porous material. This studies also highlighted the considerable capacity of biporous PHEMA materials to incorporate water compared to bulk and monoporous polymers. Indeed, these complex structures were able to incorporate until 2400 % of water in a few hours, while monoporous counterparts only incorporated 300 %. In the literature, it was demonstrated that the water uptake of scaffolds and porous monoliths did not exceed 68 %. Moreover, the pore

interconnectivity increased greatly the water uptake (by a factor of nearly 5-6). As above-mentioned, the synchrotron tomography permitted to observe the fine microstructure with 0.65 μm voxel size which is much lower than the scans made by CT (8 μm and 2 μm). This research permitted to investigate the 3-D microstructure of doubly porous polymeric networks by means of classical μCT and synchrotron μCT . The different experimental protocols and imaging devices configuration allowed a precise observation of the morphology of such materials as the pores connectivity and shape. Imaging provided also crucial information about the void/polymeric matrix interfaces which play an important role in transport properties. Three microstructural features were observed : the large pores having the NaCl particles shape, the polymeric matrix exhibiting the small pores, and thin polymeric walls. However, the quantitative analysis of the porosity was tricky because of the very thin polymeric walls and filaments which made difficult the segmentation step. Finally, some μCT and synchrotron images will be selected as input data for the computation of fluid flow through porous medium in forthcoming experiments. The interconnection in the higher porosity level was demonstrated to be crucial regarding transport properties in such biporous PHEMA-based materials as their water uptake behavior is much more important than that of their non-interconnected counterparts.
