Highlights:

- What is already known on this subject?

The relationship between the gut microbiota and Crohn's disease is clearly establish.

- What are the new findings?

A distinct bacterial dysbiosis has been observed in patients with symptomatic Crohn's disease, independent of mucosal inflammation.

- How might it impact on clinical practice in the foreseeable future?

The treatment of gut dysbiosis in Crohn's disease patient may improve their symptoms.

Key words: Crohn's disease, Microbiota, Fecal calprotectin, Symptoms, Mucosal

inflammation, Probiotic.

In inflammatory bowel diseases (IBDs), the global composition of the gut microbiota contains specific pathogens that may be relevant to the etiology and pathogenesis of the disease. Predominant changes described in the literature regarding the gut microbiota composition of individuals with Crohn disease (CD), include: alterations in the proportion of Bacteroidetes and Firmicutes, an increase in the percentage of Gammaproteobacteria and Enterobacterales (i.e. *Escherichia coli* in CD with ileal disease), and a decrease in Clostridiales (i.e. *Faecalibacterium prausnitzii*) [1,2]. Furthermore, in the paper by Sokol et al., besides bacterial dysbiosis, their study identified a distinct fungal microbiota during IBD characterized by alterations in biodiversity and composition that might play a role in IBD pathogenesis [3]. They also observed a decrease of the alpha diversity in CD, particularly in samples from flaring patients. However, the disease activity was assessed by physicians based on symptoms without objective markers of inflammation, such as fecal calprotectin (FC). A known discrepancy exists between symptoms and mucosal inflammation during CD, thus making difficult to diagnose a flare only based on symptoms [4]. Of note, irritable bowel syndrome has also been associated with a reduction of microbial diversity [5]. This remains unclear whether the decrease of bacterial diversity during a flare of CD is linked to the symptoms or the mucosal inflammation. The aim of the study was then to compare the gastrointestinal tract microbiota in CD patients during flare of CD and/or mucosal inflammation.

Stool samples from 125 consecutive adult patients with a confirmed diagnosis of CD were collected during a one-year period at the referral center Hospital University of Rennes (France) . The Harvey Bradshaw (HB) index was assessed at each time of a stool collection. CD patients were grouped for dichotomous analysis with an HB score

of ≥ 5 considered as symptomatic CD and those with an HB score < 5 as asymptomatic CD [6]. FC levels are representative of neutrophil migration into the intestinal mucosa that occurs in the process of intestinal inflammation, and in clinical practice, they are commonly used as a non-invasive biomarker that significantly correlates with inflammatory disease activity and response to therapy [7]. The FC level was measured for each sample using a fully automated chemiluminescent immunoassay (LIAISON Calprotectin, DiaSorin). The absence of mucosal inflammation was defined with a fecal calprotectin (FC) value $< 50 \mu\text{g/g}$. According to the International Human Microbiome Standards (IHMS), patients were asked to collect fecal samples immediately after defecation in a sterile container (VWR). Then, the stool samples were stored up to 24 hours at 4°C . When received at the laboratory, all samples were manually homogenized and weighed into separate aliquots for storage at -80°C until DNA extraction. The composition of microbial populations was assessed by 16S rRNA gene sequence-based microbiota analysis. DNA was extracted from fecal specimens with the automated MagnaPure (Roche Diagnostics GmbH, Mannheim, Germany) instrument, using the MagNA Pure LC DNA Kit III (bacteria, fungi) (Roche) according to the manufacturer's recommendations. Primers were designed according to the V3-V4 regions of the bacterial 16S rRNA (the upstream primer: PCR_341 F is 5'-CCTACGGGNGGCWGCAG-3', and the downstream primer: PCR_785R is 5'-GACTACHVGGGTATCTAATCC-3') [8]. The primers were linked to Illumina sequencing adapters and were used in PCR amplification; the PCR products were purified, quantified, and then normalized to form a sequencing library. These libraries first were underwent quality control and qualified libraries were sequenced by Illumina MiSeq-Using paired 250-bp reads as outlined in the Illumina 16S sample preparation guide [9]. The raw image data files obtained from the Illumina MiSeq were analyzed

and transformed into raw sequence reads by base calling, and the results were stored as FASTQ files, containing sequence information of reads and their corresponding sequencing qualities. The individual sequence reads obtained were filtered, trimmed and processed as described by Escudie and al. according to Find Rapidly OTUs with Galaxy Solution (FROGS) [10]. All reads were classified to the lowest possible taxonomic rank using FROGS and a reference dataset from the SILVA 16S database (<https://www.arb-silva.de/download/arb-files/>). A table of 16S rRNA Operational Taxonomic Units (OTUs) and an evolutionary tree were then generated while the R software (version 3.5.1) was used for all analyses. Descriptive statistics and visualization of the microbiome data were conducted in R using multiple packages, including 'phyloseq', 'microbiome', 'reshape2', 'ggplot2', 'grid', 'ape', 'scales', 'DESeq2', 'vegan', 'corrplot', 'RCy3', 'igraph' [11]. The Kruskal–Wallis test was applied to compare global composition of bacterial microbiota differences at the phylum level. The Chao1 and Shannon indices were used to assess alpha diversity. The Bray-Curtis dissimilarity matrix was used to determine beta diversity and visualized using principal coordinates analysis (PCoA) according to a variant of PERMANOVA procedure ("adonis" function in the R "vegan" package). To determine species associated with patients' symptoms, the differential abundance of bacterial species between patients was determined using DESeq2 with p-value adjusted for multiple testing using the Benjamini–Hochberg method (cut-off = adjusted $p < 0.05$). Positive log-fold change pointed out an increase in abundance, while negative log-fold change pointed out a reduction in abundance in the symptomatic patients compared to asymptomatic patients. To investigate the interactions and differences of OTUs in the two groups of patients, we computed the Pearson correlations and drew the correlation matrix and

interaction network with Cytoscape (<https://cytoscape.org/>). We used the False Discovery rate (FDR) method to adjust p-values for multiple testing.

A total of fecal microbiota from 125 CD patients, including: 25 symptomatic patients (HB index ≥ 5) with a concomitant value of FC $\geq 50 \mu\text{g/g}$; 17 symptomatic patients (HB ≥ 5) with no mucosal inflammation (FC $< 50 \mu\text{g/g}$); 59 asymptomatic patients (HB < 5) with a concomitant value of FC $\geq 50 \mu\text{g/g}$; 24 asymptomatic patients (HB < 5) with no mucosal inflammation (FC $< 50 \mu\text{g/g}$). Details regarding age, female sex, Body Mass Index (BMI) $> 25 \text{ kg/m}^2$, smoking, disease duration, gastrointestinal surgery, Montreal A, B, L, fecal calprotectin ($\mu\text{g/g}$), treatment within 90 days of microbiota analysis (Anti-TNF, Thiopurine-methotrexate (MTX)) are shown in supplementary Table 1. The global composition of bacterial microbiota at the phyla level in patients with symptoms showed lower relative abundance of Firmicutes and Bacteroidetes while the phyla Proteobacteria and Fusobacteria were more represented, independently of the FC level (i.e., $<$ or $\geq 50 \mu\text{g/g}$) (Figure 1). Interestingly, we observed no alteration of the abundance of phyla for asymptomatic CD patients (HB ≤ 4) even with FC value $\geq 50 \mu\text{g/g}$ ($p < 0.05$). The comparison of microbial community structure using alpha diversity indices showed a lower number of detected species (Chao1) as well as a lower diversity (Shannon) in symptomatic patients as compared to asymptomatic patients ($p = 0.02$). Symptomatic and asymptomatic patients also differed according to the community structures (PERMANOVA, $p = 0.002$) as well as the differential abundance analysis of the species-level taxonomic assignments regardless the FC level. The abundance of several taxa was decreased in case of symptoms, particularly within the phylum Firmicutes. The abundances of genera *Escherichia-Shigella*, *Enterococcus*, *Streptococcus*, *Megasphaera*, *Fusobacterium*, *Erysipelatoclostridium*, *Butyrivibrio*, *Gemella*, *Prevotella*, *Solobacterium*, *Lactobacillus*, *Akkermansia* were significantly

enriched in the microbiota of symptomatic patients ($p < 0.05$) (Figure 1 B). The changes in *Escherichia-Shigella* and *Streptococcus* proportions were particularly remarkable for all symptomatic patients. We further investigated the existence of correlations at the genus level according to symptoms (Figure 1 C). Symptomatic patients were more likely to present a positive correlation between the abundance of *Faecalibacterium* and *Bacteroides* ($p=4.510^{-7}$) and *Subdoligranulum* ($p=4.510^{-6}$); *Ruminococcus torques* group and *Blautia* ($p=4.510^{-6}$) and *Alistipes* and *Ruminococcaceae* UGC-002 ($p=7.710^{-3}$) (Figure 1 C1). In asymptomatic patients, a positive correlation was found between the abundance of *Escherichia-Shigella* and *Lachnoclostridium* ($p=2.710^{-4}$); *Streptococcus* and *Veillonella* ($p=1.610^{-6}$); *Ruminoclostridium* 5 and *Ruminococcus torques* group ($p=1.610^{-7}$) and *Ruminococcaceae* UCG-002 ($p=1.510^{-8}$) (Figure 1 C2). Similar results were obtained with interaction network generated using Cytoscape (data not shown) and were not affected by the absence of mucosal inflammation or not.

To our knowledge, this is the first study assessing the microbiota in patients with flare and/or FC concentration $<$ or ≥ 50 $\mu\text{g/g}$. These data underlines a distinct bacterial microbiota dysbiosis in symptomatic patients independently of the FC level. Indeed, dysbiosis was much more predominant in symptomatic patients than in asymptomatic patients with mucosal inflammation. The differential abundance of species between patients allowed us determining species signatures of symptomatic CD. *Escherichia-Shigella*, *Fusobacterium*, *Gemella* and *Streptococcus* were overrepresented in symptomatic patients. Moreover, *Ruminococcus* 1, *Lachnospira*, *Clostridium sensu stricto* 1 and *Ruminococcus* 2 were also underrepresented in symptomatic patients. The proportions of these OTUs were already described as altered in CD [12,13]. However, as those articles focused on healthy controls, they cannot be related to the

presence of symptoms. The presence of *Escherichia-Shigella* and *Streptococcus* were identified in all symptomatic patients. So, these “key microbial signatures” would help with the diagnosis of symptomatic CD. The interaction network showed that the interactions and differences of OTUs were different in the two groups of patients. Some interactions were specific to symptomatic CD and others to asymptomatic CD. In asymptomatic CD, *Escherichia-Shigella* and *Streptococcus* were positively correlated with *Lachnospirillum* and *Veillonella*, respectively. However, for symptomatic CD, *Escherichia-Shigella* and *Streptococcus* had no correlation with any other OTUs. This lack of correlation may be related to symptoms in CD patients. Furthermore, the interaction network results need to be taken into consideration when creating probiotics combination to treat CD. For instance, the probiotic combination VSL#3 (a probiotic preparation of eight live freeze-dried bacterial species, including *Lactobacillus casei*, *L. delbrueckii* subsp. *bulgaricus*, *L. acidophilus*, *L. plantarum*, *Bifidobacterium longum*, *B. infantis*, *B. breve*, and *Streptococcus salivarius* subsp. *thermophilus*) and *E. coli* Nissle, which do not take under consideration this interaction network, were shown to reduce active inflammation and sustain remission only in ulcerative colitis (UC) but not in CD [14,15]. Some limitations regarding this study should be acknowledged. The patient populations according to being symptomatic or not were broadly comparable. However, symptomatic patients without mucosal inflammation correspond to patients with older diseases or history of surgery. In conclusion, this study suggests a possible association between gut dysbiosis and the presence or absence of Crohn's disease symptoms, independently of fecal calprotectin levels. These microbial signatures linked to symptoms may be taken into account when planning to evaluate the efficacy of probiotics or fecal microbiota transplantation in the treatment of Crohn's disease.

FIGURE LEGENDS

Figure 1.

- A. Global composition of bacterial microbiota at the phyla level. Symptomatic CD was defined according to the Harvey Bradshaw Index (HB) ≥ 5 .
- B. Significant ($p < 0.05$) log-fold changes in the abundances of bacterial species in symptomatic patients.
- C. Correlation matrix between bacterial groups in symptomatic patients (C1) and asymptomatic patients (C2). Positive values (green rounds) indicate positive correlations, and negative values (red rounds) indicate inverse correlations. The shading of the round indicates the magnitude of the association; darker rounds are more strongly associated than lighter rounds. The sign of the correlation was determined using Spearman's method.
