ABSTRACT

Background: Systemic right ventricle (RV) is a rare and complex form of congenital heart disease (CHD) with a prognosis related to RV dysfunction and impaired physical capacity. Routine follow-up relies on echocardiography, however the prognostic value of echocardiography parameters remains under debate. Real-life patient follow-up involves different ultrasound systems. We aimed to evaluate echocardiography parameters' reliability in systemic RV, in terms of reproducibility, using vendor-independent software, and in terms prediction of physical capacity impairment.

Methods: Adult patients with D-transposition of the great artery (d-TGA) who underwent atrial switch or with congenitally corrected TGA (cc-TGA) were included in this multicentre prospective study. Current echocardiography parameters were analysed using TomTec-Arena™ software. Intraclass correlation coefficients (ICC) assessed inter- and intraobserver reliability. Associations between the most reproducible echocardiography parameters and exercise capacity (peak VO₂, VE/VCO₂ slope) were explored.

Results: A total of 47 patients were included in the study (87% d-TGA, median age 36.4 ± 8 years). Conventional and 2D strain echocardiography parameters indicated the existence of a RV dysfunction (TAPSE = 12.8 ± 3.1 mm; RV free wall longitudinal 2D strain = -13.6 ± 3.9%). Good reproducibility (ICC > 0.75) for both intra and inter-observer variability was observed in 8 RV echocardiography parameters. Only the TAPSE was significantly associated with peak VO₂ (r = 0.4, P = 0.02).

Conclusions: In this prospective study mimicking real-life echocardiography follow-up of systemic RV, TAPSE, RV free wall longitudinal 2D strain and peak systolic S wave, were the most reproducible echocardiography parameters. However, only the TAPSE was associated with peak VO₂.

1. Introduction

Among all types of congenital heart diseases (CHD), the systemic right ventricle (RV) represents a rare and complex form, accounting for approximately 10% of all CHD [1]. In patients with two ventricles, the systemic RV may be observed in two situations: dextro-looped

transposition of the great arteries (d-TGA) after atrial switch procedure (Mustard, Senning) and congenitally corrected TGA (cc-TGA) [1–4]. In a normal heart, the RV is a compliant pump providing the low-pressure pulmonary output, whereas the systemic RV provides, by definition, the high-pressure systemic output. However, the RV is not intrinsically adapted to pump against the high-pressure level developed by the

systemic circulation, as its fibro-muscular architecture, shape and function, are far different from those of a left ventricle [5–7]. Therefore, most patients with a systemic RV are prone to present with late complications such as heart failure, significant tricuspid regurgitation, or sudden death due to ventricular arrhythmia [1,8–11]. Moreover, patients with a systemic RV will experience a gradual and inexorable decline in their physical capacity, and both maximum oxygen uptake (VO_2) and ventilatory efficiency (VE/VCO_2 slope), measured during a cardio-pulmonary exercise test (CPET), are associated with disease severity [12–14]. Indeed, these two CPET parameters correlate with prognosis and health-related quality of life in chronic heart failure, including in patients with CHD [14–16], and we recently reported the relevance of CPET for clinical severity assessment in adult patients with a systemic RV [12].

In the routine follow-up, assessment of systemic RV function predominantly relies on transthoracic echocardiography. Cardiac magnetic resonance (CMR) imaging has been considered as the reference method for RV function assessment in such patients [17]. However, compared to echocardiography, CMR is less available, more costly, and more difficult to perform in patients with pacemaker or implantable defibrillator. Moreover, results of studies comparing CMR and echocardiography in systemic RV remain controversial [18–20], and there is currently still a debate on which echocardiography parameter best predicts the patient outcome, especially in terms of physical capacity [21,22]. Furthermore, as opposed to most research studies on cardiac imaging, real-life patient follow-up usually involves examinations performed by different sonographers, on different ultrasound systems.

In this prospective multicentre study, we aimed to evaluate the reliability of echocardiography parameters in a cohort of patients with a systemic RV, in terms of reproducibility, using a vendor-independent software, as well as in terms of prediction of physical capacity impairment.

2. Methods

2.1. Study design and population

This multicentre cross-sectional study was carried out from June 2017 to April 2019 in three tertiary care CHD centres in France and Belgium (centre 1: Bordeaux University Hospital, France; centre 2: Montpellier University Hospital, France; centre 3: Cliniques Universitaires Saint-Luc, Brussels, Belgium).

Adult patients (≥ 18 years) with a systemic RV were screened during their routine follow-up. Patients with a single ventricle physiology were not eligible (double inlet right ventricle with previous Fontan palliation, and hypoplastic left heart syndrome palliated with the Norwood-Fontan protocol). Therefore, two groups of patients with systemic RV were eligible for the study: d-TGA after atrial switch procedure (Mustard, Senning) and cc-TGA. Patients willing to participate in the study were required to undergo the following examinations in one of the three participating CHD centres: physical examination, electrocardiogram (ECG), transthoracic echocardiography, laboratory testing, and CPET.

2.2. Clinical and paraclinical parameters

The following clinical variables were collected: gender, age, weight, height, body mass index (BMI), NYHA functional class, and the type of systemic RV (d-TGA or cc-TGA). The electrocardiographic status (pacemaker, implantable defibrillator), and laboratory parameters (N-terminal pro-brain natriuretic peptide (NT-proBNP)) were collected.

2.3. CPET parameters

The main prognosis outcome selected in this study was the exercise capacity evaluated by a CPET, and represented by two major parameters: the peak VO_2 and the VE/VCO_2 slope.

As in our previous studies using CPET procedures, all centres used a

similar cycle ergometer triangular protocol to obtain a homogeneous incremental overall duration between 10 and 15 min: a 1-min rest; a 3-min warm-up (10–20 Watts) in increments of 10, 15, or 20 W each minute; a pedalling rate of 60–80 revolutions per minute; a 3-min active recovery (20 W); and a 2-min rest [12,23,24]. The exercise test was considered as maximal when 3 out of the 4 following criteria were reached: respiratory exchange ratio ($\text{RER} = \text{VCO}_2/\text{VO}_2$) ≥ 1.1 , maximum heart rate $>85\%$ of maximal age-predicted heart rate, limit of the patient's tolerance despite verbal encouragement, plateau of VO_2 ($\text{VO}_{2\text{max}}$) despite the increasing exercise intensity. When the oxygen uptake did not reach a plateau, which is very common in adult patients with a systemic RV, the peak VO_2 was reported. Peak VO_2 values were normalized in a percentage of the predicted $\text{VO}_{2\text{max}}$ using reference values for cycle ergometer test in the general adult population (named as percent-predicted peak VO_2) [25,26]. The ventilatory efficiency, e.g. the VE/VCO_2 slope, was determined using linear regression of minute ventilation (VE) and CO_2 production (VCO_2) [14,27].

2.4. Echocardiography parameters

In order to reproduce real-life practice, all eligible patients were consecutively enrolled, regardless echogenicity. We did not use any contrast agents. Echocardiography recordings were prospectively stored in DICOM format and offline analyses were performed by an investigator (C.B., senior congenital cardiologist) who was blinded to clinical and CPET data. A second analysis was performed on all recordings, by the same investigator (C.B.) to assess intraobserver reproducibility, and by a second investigator (V.P., fellow) to assess interobserver reproducibility, with no access to the results of first analysis. Echocardiography analyses for 2D strain parameters were performed using TomTec Arena™ version 40 (TomTec Imaging Systems GmbH, Unterschleissheim, Germany) software, a vendor-independent program that can measure all echocardiographic images stored in DICOM format.

The following RV function parameters were measured, following the recommendations of the American Society of Echocardiography and the European Association of Cardiovascular Imaging [28] and commonly used in systemic RV [18](19): tricuspid annular plane systolic excursion (TAPSE), tricuspid annular diameter, and fractional area change (FAC), from the apical 4-chamber view. Severity of tricuspid regurgitation (TR) was semi-quantitatively graded with colour Doppler method as none, mild, moderate, or severe [29]. Doppler method was used to measure dP/dt defined as the time required for the tricuspid valve regurgitation jet to increase velocity from 1 to 3 m/s, from the ascending limb of the TR continuous-wave Doppler signal. Systemic subaortic velocity time integral (VTI) and the myocardial performance Tei index were obtained using pulsed-wave Doppler. The Tei index was defined as the sum of the isovolumic contraction and the isovolumic relaxation time divided by ejection time [30]. Systolic excursion velocity (S) and isovolumic acceleration (IVA) were measured using pulsed Doppler Tissue Imaging, with Doppler sample volume placed in the tricuspid annulus of the RV free wall [19]. Aortic, mitral and pulmonary regurgitation were semi-quantitatively graded. Inferior vena cava (IVC) diameters (maximum and collapse index) were measured using M-mode echocardiography.

Speckle tracking echocardiography was used to measure RV longitudinal 2D strain, using two different methods from the two available TomTec Arena™ version 40 software algorithms: one designed for the left ventricle (LV) and the other one designed for the RV. The RV was visualized from the apical 4-chamber view. Using the LV software algorithm, the RV was divided into 3 free wall segments (basal, mid, apical) and 3 interventricular septum segments (basal, mid, apical) (Fig. 2). Using frame rates of 60–80 frames/sec to optimize myocardial deformation analysis, 2D strain analyses were performed for each segment, globally for the RV free wall, globally for the interventricular septum, and globally for the entire RV. As the LV software algorithm is initially dedicated to LV contouring, three markers were manually positioned at

the RV extremities (apex, tricuspid annulus extremity towards the RV free wall, and tricuspid annulus extremity towards the septum), in order to “force” automatic RV contouring. Using the RV software algorithm, the RV was only divided into 3 free wall segments (basal, mid, apical) (Fig. 3). 2D strain analyses were performed for each segment, and globally for the RV free wall. The RV peak systolic strain was calculated by the software. After positioning 3 markers at the RV extremities (apex, tricuspid annulus extremity towards RV free wall, and tricuspid annulus extremity towards the septum), the RV software algorithm automatically tracked the RV endocardial contour. End systole was defined by aortic valve closure and was automatically recorded by the software. For each software algorithm, tracking was verified and corrected if necessary, by manually adjusting the contour to ensure optimal tracking.

To define altered RV function, we used cut-off values recommended by the American Society of Echocardiography and the European Association of Cardiovascular Imaging: TAPSE <17 mm, peak S wave <9.5 cm/s, FAC <35%, RV free wall longitudinal 2D strain < -20%, and Tei index >0.43 [28].

2.5. Formal aspects

The study was conducted in compliance with the Good Clinical Practices protocol and Declaration of Helsinki principles. The Ethics Committee Nord-Ouest II in France and the UCL Ethics Committee in Belgium approved the study, which was registered on [ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT03379831) (NCT03379831). Informed consent to participate in the study was obtained from all patients.

2.6. Statistics

The study population was described using means and standard deviations (SD) for quantitative variables. For qualitative variables, frequencies and their associated percentage were used. The continuous variable distributions were tested with the Shapiro-Wilk statistic. Quantitative variables were compared using Student's t-test when the distribution was Gaussian and using the Mann-Whitney test otherwise. For qualitative variables, groups were compared using the chi-squared test or Fisher's exact test.

To evaluate inter and intra-observer reliability, intraclass correlation coefficients (ICC) were used. As defined by Koo et al., values less than 0.5, between 0.5 and 0.75, between 0.75 and 0.9, and greater than

0.90 were indicative of poor, moderate, good, and excellent reliability, respectively [31].

The association between echocardiography variables and the three CPET parameters (peak VO₂, the percent-predicted peak VO₂ and the VE/VCO₂ slope) was explored by the Pearson correlation coefficient for normal quantitative variables.

The statistical significance was set at 0.05 and analyses were performed using Statistical Analysis Systems Enterprise Guide version 4.3 (SAS Institute, Cary, NC, USA).

3. Results

3.1. Patients

During the study period, 52 eligible patients were consecutively screened in the three participating centres. Because of poor echocardiographic image quality, five patients were not included (Fig. 1). A total of 47 subjects (mean age 36.4 ± 8 years; 66% male) with a systemic RV were enrolled in the study, in Bordeaux University Hospital (n = 26), Saint-Luc University Hospital (n = 14), and Montpellier University Hospital (n = 7). More than two-thirds of the patients had undergone Senning atrial switch for d-TGA and only 13% of the patients had a cc-TGA. Most patients were in NYHA functional class I or II, but had an impaired exercise capacity with a reduced peak VO₂ and elevated VE/VCO₂ slope (Table 1).

3.2. General echocardiography parameters

Echocardiography examinations were performed on two different ultrasound systems, equally divided between EPIQ7 ultrasound (Philips Healthcare) for 24 patients and Acuson SC2000 ultrasound (Siemens Healthcare) for 23 patients.

Conventional and 2D strain echocardiography parameters indicated the existence of a RV dysfunction with a mean TAPSE value of 12.8 ± 3.1 mm and a mean RV free wall longitudinal 2D strain value of -13.6 ± 3.9 %, derived from the RV algorithm. Severe forms of RV dysfunction were not predominant, with severe TR observed in only 4 patients and baffle obstruction in only 2 patients. Overall, significant additional anatomic lesions such as LV outflow tract obstruction, pulmonary stenosis, and baffle leaks, were not observed. After atrial switch repair, baffle stenosis was reported for only two out of 41 patients

(Table 2).

3.3. Reproducibility of RV echocardiography parameters

Intraobserver reproducibility was good to excellent for nearly all RV conventional and 2D strain echocardiography parameters (all ICCs >0.75 , $P<0.001$). Only the Tei index and the apical septal 2D strain using RV strain software algorithm showed a moderate reproducibility (ICCs were 0.60 and 0.70 respectively, $P<0.001$).

Interobserver reproducibility was good to excellent (ICCs >0.75 , $P<0.001$) for three conventional parameters (TAPSE, peak systolic S wave and dP/dt). Very poor reproducibility was observed for the Tei index and the IVA (ICCs <0.10). Interobserver reproducibility was

globally better for 2D strain parameters, especially with the RV speckle tracking software algorithm. Interestingly, all free wall RV longitudinal 2D strain values using RV speckle tracking software algorithm presented a good reproducibility (ICCs >0.75 , $P<0.001$), whereas only one value (global free wall) presented a good interobserver reproducibility with the LV speckle tracking software algorithm (Table 3).

Overall, eight RV echocardiography parameters had a good reproducibility, with ICCs >0.75 for both intra and interobserver variability: TAPSE, free wall RV longitudinal 2D strain using RV speckle tracking software algorithm (apical, basal, medial and global segments), free wall global RV longitudinal 2D strain using LV speckle tracking software algorithm, peak systolic S wave, and tricuspid dP/dt .

3.4. Correlation between most reproducible echocardiography RV parameters and physical capacity

When measuring the association between those eight most reproducible RV echocardiography parameters and the CPET parameters, we found that only the TAPSE presented a significant correlation with peak VO₂ ($r = 0.40$, $P = 0.02$). The association between RV longitudinal 2D strain using RV speckle tracking software algorithm and peak VO₂ was moderate and did not reach statistical significance ($r = 0.23$, $P = 0.14$). No association was found between any RV echocardiography parameter and the VE/VO₂ slope (Table 4).

4. Discussion

In this prospective multicentre study, from a cohort of adult patients with a systemic RV, good reproducibility was found in most conventional and 2D strain RV echocardiography parameters. In order to best match the reality of clinical follow-up, our study analysed echocardiography examinations performed by different sonographers, on different ultrasound systems, and used, for the first time in this population, the Tom-Tec-Arena™ vendor-independent software for 2D strain analysis.

Among all echocardiography parameters tested in this study, the

Legend: TAPSE, tricuspid annular plane systolic excursion; LV, left ventricle; RV, right ventricle; TDI, tissue Doppler imaging.

TAPSE appeared to be the only predictor of physical capacity in systemic RV, with very low intra and inter-observer variability (ICC of 0.97 and 0.86, respectively). Indeed, the TAPSE is easily measurable in M-mode from the apical 4-chamber view, even if image quality is mediocre or endocardial border recognition is difficult, as opposed to strain and FAC measures [6,32]. Moreover, in our study, the TAPSE was significantly correlated with peak oxygen uptake, which is considered as a major prognosis parameter in systemic RV [13]. This is in line with the recent study from Gavotto et al., showing an association between TAPSE and percent-predict peak VO2 ($r = 0.40$; $P < 0.001$) from a cohort of 111 patients with a systemic RV [12]. Similarly, Winter et al. reported that TAPSE was significantly associated with peak VO2, NYHA functional class and NT-proBNP in a cohort of 50 patients [33]. As in our study, the TAPSE was the only echocardiography parameter correlating with physical capacity. Moreover, Lissin, et al. found a correlation between TAPSE and CMR assessments of systemic RV function ($r = 0.66$, $P = 0.01$) [18]. More generally, in many pathologies affecting the RV, the TAPSE has shown some interest in terms of RV function follow-up or even as a prognosis biomarker, such as in pulmonary arterial hypertension [34], or

pulmonary embolism [35]. In the natural history of systemic RV, Petersen et al. have described the existing shift from longitudinal myocardial fibres to circumferential myocardial fibres [7]. As the TAPSE reflects the RV longitudinal contraction developed by longitudinal myocardial fibres, it therefore correlates with systolic dysfunction in systemic RV. The normal values for TAPSE in systemic RV are known to be lower than in normal sub-pulmonary RV [36]. Therefore, decrease in longitudinal function, which TAPSE reflects, could be to some degree an adaptive process and not a real impairment of RV function.

Then, our study found that reproducibility of RV longitudinal 2D strain was good, globally and for each segment. Moreover, using for the first time both LV and RV TomTec-Arena™ software algorithms in systemic RV, we observed the lowest variability for the RV free wall global longitudinal 2D strain with the RV software algorithm (ICC of 0.98 and 0.79 for intra and inter-observer variability, respectively). The systemic RV has a function similar to a LV, however its shape remains close to a normal sub-pulmonary RV. Therefore, the RV software algorithm from TomTec-Arena™ appeared to be well adapted to 2D strain analyses in systemic RV. The recent study from Ladouceur et al. on a similar

population found good interobserver reproducibility (ICC of 0.93) of RV global longitudinal 2D strain using LV software algorithm [21]. However, in this retrospective study, echocardiography examinations were performed by a single examiner, on a single ultrasound system and off-line analyses were performed on a vendor-dependant software (EchoPAC, General Electric Healthcare).

Unfortunately, despite this good reproducibility, the association between RV free wall global longitudinal 2D strain (using the RV software algorithm) and peak VO2 in our study did not reach statistical significance ($r = 0.23$; $P = 0.14$), probably because of a low sample size. Indeed, previous studies found a significant association, in patients with systemic RV, between RV free wall global longitudinal 2D strain and peak VO2 ($r = 0.42$; $P = 0.007$) [21], clinical events [37] or RV ejection fraction [38, 39].

Both TAPSE and RV free wall longitudinal 2D strain reflect RV longitudinal function and both proved to be reproducible according to our study results. Nevertheless, only the TAPSE correlated with peak VO2. In various pathologies affecting the RV, such as pulmonary hypertension, TAPSE has been the most popular measure used as a surrogate for RV longitudinal systolic function, with a high proven prognostic significance [40]. Despite being a load-dependent and angle-dependent parameter reflecting mainly the lateral wall longitudinal motion, the TAPSE's widespread use is also due to its simplicity of acquisition, and its high reproducibility with low inter-operator variability [41]. Speckle tracking echocardiography has more recently emerged and shown promising RV contractility evaluation results. Although regional and global 2D strains are load and angle-dependent measurements [42], several clinical studies in pulmonary hypertension have shown their prognostic value with an acceptable inter and intraobserver variability [43]. In systemic RV, the prognostic value of 2D strain may be limited by the great heterogeneity in terms of RV shape.

Finally, our study provided original data on the variability of all the remaining RV echocardiography parameters. Three variables had a good reproducibility (tricuspid dP/dt , peak systolic S wave, and IVC expiration diameter), but were not correlated with any CPET data. In particular, the peak systolic S wave was one of the most reproducible parameters in this study, considering both inter and intra observer variability (ICCs of 0.92 and 0.90, respectively). This remains controversial in the literature. Indeed, the peak systolic S wave has been correlated with RV dysfunction [19] or percent-predict peak VO2 in systemic RV [12]. Conversely, three variables (FAC, Tei index and IVA) have shown poor reproducibility in our study. Yet, some previous studies have observed an association between those parameters and CPET or RV dysfunction, however none has investigated their reproducibility. For instance, Kalogeropoulos et al. reported a correlation between FAC and RV ejection fraction assessed by CMR in systemic RV [37]. Guidelines from the American Society of Echocardiography (ASE) have commented on the interest of FAC in RV function assessment [44], but one of the two provided references found only a weak correlation between FAC and RV ejection fraction assessed by CMR [45]. Measuring FAC may be challenging as the RV contouring beneath the trabeculations is difficult and requires a good apical-4C view to see the apex, unlike the TAPSE. Reports on the Tei index remain controversial, some studies claiming its interest in pulmonary arterial hypertension [30,46], and others showing the absence of any correlation with clinical events [19,37]. The reliability of IVA analysis had not been previously reported in systemic RV, to our knowledge. This parameter has shown some interest for RV assessment before cardiac surgery [47], however no association with clinical events has been established in previous studies [37].

4.1. Study limitations

The low sample size may have resulted in the lack of statistical significance in the association between some echocardiography parameters and CPET parameters, especially for RV longitudinal 2D strain. Moreover, we plan to carry out a larger prospective study to identify TAPSE

cut-off values to predict RV dysfunction in systemic RV.

5. Conclusions

This prospective study attempted to reflect real-life follow-up of patients with systemic RV, involving different sonographers and different ultrasound systems. We found that the TAPSE, the global RV free wall longitudinal 2D strain, and the peak systolic S wave were the most reproducible echocardiographic parameters. However, only the TAPSE was associated with peak VO2. Further studies should determine whether the TAPSE could be used as a predictor of prognosis.

ClinicalTrials number

NCT03379831.

Acknowledgement of grant support

This work was funded by Montpellier University Hospital Clinical Research Program (AOI-UF8745). XI and JBT were supported by the French Government as part of the "Investments of the future" program managed by the ANR, National Research Agency [Grant reference ANR-10-IAHU-04].

Declaration of competing interest

The authors declare that there is no conflict of interest.

Acknowledgments

We thank our patients for their participation in the study and our CPET laboratory technicians for their work.
