Abstract

The present paper is specifically focused on enclosed or semi-enclosed basins where the wind is the dominant driver of water surface tilting, leading to the so-called wind tide contributing to water levels rise. Wind-induced free surface tilting is studied using the 1-D steady form of the depth-averaged shallow water (Saint-Venant) momentum equation which reflects the depth-averaged local balance between surface slope and wind stress. Two contrasted field sites, the Berre and Vaccarès lagoons, have been monitored providing water level data along a reference axis. This study highlighted the occurrence of wind tides at the two field sites. The bimodal wind exposure ensured the robustness of the observations, with non-linear but symmetric behaviors patterns observed in winds from opposite directions. It is observed that the higher the wind speed, the steeper the slope of the free surface in accordance with the well known basic trend. In addition, a significant effect of depth is observed, with greater surface tilting in the shallower lagoon. The data analysis confirmed the robustness of such a simple approach in the present context. Using the additional assumption of constant, i.e. wind-independent, drag coefficients (C_D) allowed a good match with the observations for moderate wind speeds for both sites. However, the depth effect required the C_D to be increased in the shallower basin. Classical empirical wind-dependent C_D parameterizations provide better wind-tide predictions than the constant- C_D approach in very strong wind conditions but totally failed in predicting surface tilting in the shallower site, suggesting that physical parameters other than wind speed should be taken into account for the C_D parameterization in very shallow lagoons.

Keywords: wind tide, coastal lagoon, shallow water, wind stress, drag coefficient

1. Introduction

Coastal lagoons are complex systems, with high ecological and socio-economical stakes. Understanding the dynamics of water level in coastal lagoons is of primary interest for neighbouring infrastructures, inhabited and cultivated areas. When widely connected to the open sea, the lagoon water levels are influenced by large scale variations of offshore level, such as astronomical tides or surges driven by low pressure and/or wind systems. An important process is associated to the direct effect of wind on the lagoon surface. The wind stress applied on the lagoon water surface induces a tilting of the whole water body, leading to the so-called wind tide. This effect can be important in many coastal lagoons which are often shallow and partially-enclosed basins and therefore may contribute to flooding of low-lying areas. The present paper is specifically dedicated to improve our physical understanding of wind tides in enclosed or semi-enclosed basins where the wind is generally the dominant driver of water surface tilting.

A series of studies have been carried out to quantify, understand and model wind tides in the field. Among them, we can cite Kenney (1979) in Lake Winnipeg in Canada, Hellström (1941); Platzman (1963); Keulegan (1953); Gillies (1959) in Lake Erie in Canada and the United-States, Farrer (1957); Kivisild (1954); Saville (1952) in Lake Okeechobee in the United-States, Harris (1957); Platzman (1965); Hugues (1965) in Lake Michigan in the United-States, Nomitsu (1935); Hayami et al. (1996) in Lake Biwa in Japan, Nomitsu (1935) in Lake Kariba in Zambia and Zimbabwe, De Lauro et al. (2018) in Venice lagoon in Italy or Metler et al. (1975) in Lake Balaton in Hungary. In order to provide estimates of the observed wind tide in relation to wind and basin features, some well-documented examples using in-situ and modelled data are summarized in table 1. A wide range of values is observed between the different sites, related to differences in basin dimensions, wind speed and other local features. Berre and Vaccarès lagoons in France have been selected in the present research work to specifically characterize wind tides in shallow water basins. It can be brought to attention that, for any motion at the basin scale such as the wind tide, most of coastal lagoons can be considered as shallow, i.e. where the typical horizontal length scale (wind tide wave length) is very large compared to the mean depth. The main dynamics can therefore be represented by the classical shallow water depth-averaged equations. An additional issue related to the shallowness is to assess the depth effect on the wind-wave development, which should in turn affect the sea state, the surface drag and therefore the wind tide amplitude. To address this issue, the two sites (the Berre and Vaccarès lagoons) have similar wind exposure but different levels of shallowness, allowing us to test the validity of surface drag parameterization developed in deep environments and to identify a potential depth-effect on surface drag and wind tide. First estimations of wind tide in Berre and Vaccarès lagoons presented in table 1 have been inferred from existing numerical modelling studies, non specifically devoted to wind tide and water tilting processes (Leredde et al., 2002; Alekseenko, 2013; Boutron et al., 2015).

A first theoretical prediction of wind-induced mean water level variations in shallow basin can be obtained by using the 1-D steady form of the depth-averaged shallow water (Saint-Venant) momentum equation (equation 1) (Hellström, 1941). This equation reflects the depth-averaged local balance between surface slope and wind stress.

$$\frac{\partial \zeta}{\partial x} = \frac{\tau}{\rho_w g h} \quad (1)$$

Study	Length (km)	Width (km)	Averaged depth (m)	Wind speed (m/s)	Wind tide (m)	Surface slope (cm/km)	Data type

Table 1: Examples of studies on wind tides in enclosed and semi-enclosed basins

Where ζ is the free surface elevation (m), x is the spatial component in the wind direction (m), h the average water depth (m), ρ_w the water density ($kg.m^{-3}$) and g the acceleration of gravity ($m.s^{-2}$). The wind stress τ ($N.m^{-2}$) is generally inferred from a quadratic drag law (equation 2).

$$\tau = \rho_a C_D V_e^2 \quad (2)$$

where C_D is the dimensionless surface drag coefficient, ρ_a the air density ($kg.m^{-3}$) and V_e is the x-component of the wind 10 meters above sea level ($m.s^{-1}$).

Equation 1 shows that wind tide, i.e. the wind-induced variation of mean water level, is expected to increase with increasing basin length, increasing wind speed and decreasing water depth. A common simplification is to assume a spatially-uniform wind over the considered basin, leading to a constant stress for a uniform bathymetry. The water surface is consequently linear with a constant slope S (equation 3).

$$S = \frac{\partial \zeta}{\partial x} = \frac{\Delta \zeta}{L} \quad (3)$$

Where L is the basin length (m) in the wind direction i.e. the fetch and $\Delta \zeta$ the surface tilting (m).

Following this approach, which will be adopted in the following analysis, only two measurement

points are required to characterize the surface tilting and to analyse its dependency on wind features and basin parameters. The validity of such simple conceptual framework in real cases will be discussed later on.

A key parameter in equation 1 is the surface drag coefficient C_D which integrates a wide range of small-scale processes related to wave development, surface roughness and atmospheric boundary layer stability into a single bulk quantification of the energy transfer from the wind to the water mass. C_D can be inferred from macroscopic estimation of the momentum relating the wind and the surface tilting (equation 1) or obtained by local measurements of the turbulent stress. A typical order of magnitude for C_D is $1.2 \cdot 10^{-3}$ (Pugh and Woodworth, 2014) but it is known to be affected by a number of processes and the definition of an universal parameterization remains an active challenge. The main trend is that C_D increases with surface roughness which increases with wind speed due to wave development (Powell et al., 2003). Various empirical wind-dependent formulations have been proposed for C_D (Wu, 1969, 1980; Garratt, 1977; Babanin and Makin, 2008). A decrease in C_D for extreme wind speed (higher than 33 m.s^{-1}) was found because the sea surface roughness becomes saturated Powell et al. (2003). These formulations all assume that the drag coefficient is constant in space, i.e. that the length scale for surface roughness development is negligible compared to the basin scale. Moreover, the depth effect is also neglected, which presupposes that the surface roughness is not affected by depth.

Most of the wind tide studies and C_D parameterizations have been carried out in large scale and/or deep basins. Despite their ubiquity and socio-ecological importance worldwide, smaller scale shallow lagoons remain sparsely documented. The question arises of the validity of the common C_D parameterization and related theoretical estimation of wind tide through equation 1 in the context of shallow lagoons. In order to address this issue with generalizable observations, the present study is based on the comparative analysis of long-term water level data in two semi-enclosed basins geographically close and exposed to similar wind conditions but with different morphological configurations. Field sites and methods are presented in Section 2. In-situ data are presented and compared with existing formulations in Section 3, while the processes involved and the overall validity of the theoretical framework are discussed in Section 4.

2. Field experiments

2.1. Field sites

The Berre and Vaccarès lagoons (figure 1) are shallow coastal lagoons located in the eastern part of the Gulf of Lion, on the Mediterranean coast of France. This region is characterized by intense and frequent wind events. The dominant wind forcing is from N to NW with strong winds associated with an anticyclonic regime and canalized through the Rhône and Aude valleys (Mistral and Tramontane). The region is also exposed to wind from nearly opposite directions, coming from east/south-east, during low pressure and wet conditions. In both regimes, mean speed during wind events ranges between 11 and 14 m/s, with maxima over 20 m/s (Ullmann, 2008). This bimodal and strong wind exposure makes this area a well-suited environment for studying wind-driven processes.

In the present study, the Berre and Vaccarès lagoons have been monitored to understand the effect of morphology, depth and wind exposure on the mean water level dynamics. Both sites are exposed to the same synoptic wind patterns with local adaptations but show differences in terms

of size and depth : Vaccarès lagoon is shorter, wider and shallower than Berre lagoon, enabling us to study the depth-effect on the response to wind events. Main morphological characteristics of the study sites are summarized in table 1 and depicted in figures 1.b and 1.c . Numerical studies have been recently carried out to describe water mass circulation at both sites, mainly for water quality issues (Boutron et al., 2015; Alekseenko, 2013). These studies provides first estimates of the surface tilting for selected wind conditions using common wind stress parameterization but dedicated long-term in-situ documentation was still required to properly assess the wind tide development over a wide range of wind conditions.

Figure 1: Maps of field sites in south-eastern France (1.a), Vaccarès (1.b) and Berre (1.c) lagoons, bed elevation in NGF referential (official levelling network in metropolitan France).

Berre lagoon is situated in an urbanized and industrial area and flooding is a major problem. Moreover, the EDF hydroelectric plant at Saint-Chamas sporadically discharges large quantities of fresh water and silt into Berre lagoon at high volumes, up to more than once the volume of the lagoon per year. Berre lagoon can be classified as a choked coastal lagoon (Mahapatro et al., 2013)

with a restricted communication with the sea via the Caronte channel, a channel with a maximum width of about 200 meters, 6 km long and with a bathymetry between 7 and 10 m., see figure 1.c and further details in Section 2.2.2.

Vaccarès lagoon is located in the national nature reserve of the Camargue and is therefore preserved and not urbanized. The communication with the sea is more complex than in Berre lagoon because Vaccarès lagoon communicates mainly with the Impériaux system and also with Lion/Dame lagoons according to Boutron et al. (2015) (figure 1.b). Communication with the sea of the entire hydrosystem is controlled at Saintes-Marie-de-la-Mer (SMM) by 13 manual sluice gates of relatively moderate size (1 to 1.2 m), see Section 2.2.2 for additional information.

2.2. Data and instrumentation

2.2.1. Wind data

Wind data for Berre lagoon were provided from March 2019 to August 2020 by three-hourly wind measurements at the Marignane meteorological station (Météo-France), see figure 1.c. These observational data are obtained from the international surface observation messages (SYNOP) circulating on the global telecommunication system (GTS) of the World Meteorological Organization (WMO). Wind data for Vaccarès lagoon were provided from July 2019 to August 2020 by hourly wind measurements at the Tour-du-Valat station (Météo-France), see figure 1.b. For both wind data sources, the average wind speed data are the average over the last 10 minutes before the selected time with a sampling period of 1 minute. In addition, these meteorological stations also provide gust velocity data defined as extreme speed values over a period of 1 minute measured over the previous 10 minutes. Due to the proximity and the absence of significant local reliefs between measurement stations and measurement sites, the recovered wind data at Tour-du-Valat and Marignane stations are considered very representative of the wind forcing encountered at Vaccarès and Berre lagoons, respectively. Finally, at Berre, the three-hourly wind measurements are directly synchronized with our three-hourly water level measurements described below while at Vaccarès the hourly wind data are further averaged over three hours to get the synchronicity.

Wind statistics during both measurement campaigns are depicted in figure 2. Two dominant wind regimes are observed: NW or NNW winds (mistral) and SE winds. Strong wind conditions can be observed at both studied sites with wind speeds that can be higher than 20 m/s.

The mistral is generally more western and faster at Berre lagoon (Marignane station) than at the Vaccarès lagoon (Tour-du-Valat station). This difference is explained by the location of the Marignane station, about 60 km to the east of Tour-du-Valat station and therefore closer to the mouth of the Rhône valley through which the mistral is channeled (Jacq et al., 2005; Obermann-Hellhund and Ahrens, 2018).

2.2.2. Water level data

Measurement setup

Water level in Vaccarès lagoon was monitored at two distinct stations from July 2019 to August 2020. The measurements were carried out by two pairs of piezometers (Keller DCX-22AA) deployed in the north-west (VACC_NO station) and the south-east (VACC_SE station) parts of the lagoon to provide long-term pressure and temperature measurements both in the air and in the water. Station locations depicted in figure 1.b were determined based on prevailing wind conditions but

Figure 2: Wind roses for Vaccarès (Tour-du-Valat station, hourly data over 13 months) and Berre (Marignane station, tree-hourly data over 17 months) lagoons. Wind roses show the occurrence of wind directions as well as their speeds for both sites : in Vaccarès lagoon main wind directions are NNW and SE up to 20 m/s, and in Berre lagoon, NW winds over 20 m/s and SE up to 20 m/s.

constrained by the shallow bathymetry and private properties that prevented direct access to the shoreline. Sampling period at both station is 10 min.

Water level data in Berre lagoon are provided by HTM-NET network (<https://htmnet.mio.osupytheas.fr>), a network of instruments providing long term air and water pressure and temperature measurements along the French south-east Mediterranean coast (Rey et al., 2020). The data used for the present study was recorded from March 2019 to August 2020 with a similar setup as for Vaccarès, i.e. two pairs of piezometers (Keller PAA-36Xiw CTD). The two Berre lagoon stations were located at Saint-Chamas and Le Jaï harbours (see figure 1.c), i.e. roughly in the dominant wind axis, to provide pressure and temperature data every 2 minutes.

For both sites, stations were repeatedly positioned using a RTK DGPS and the processing was carried out using the Bernesse GNSS Software (Dach et al., 2015) with data from the permanent Geodesic Network (RGP) of IGN. The vertical positioning uncertainty is estimated at approximately 20 mm.

Measurement station information for Vaccarès and Berre lagoons is summarized in table 2.

Lagoon	Station name	X Easting RGF93	Y Northing RGF93	Sampling period (min)	Start of study time	End of study time
Berre	Le Jaï	877723.4	6262302.3	2	2019-03-22	2020-08-28
	Saint-Chamas	863587.3	6274333.3	2	2019-03-22	2020-08-28
Vaccarès	VACC_NO	824113.3	6274390.3	10	2019-07-09	2020-08-25
	VACC_SE	830229.5	6270643.0	10	2019-07-09	2020-08-25

Table 2: Stations information in Berre and Vaccarès lagoons: names, locations and data acquisition parameters

Water level calculation

The pressure difference between air and water offers the means to determine the water level variation, based on the assumption of hydrostatic pressure (equation 4):

$$\zeta = \frac{\Delta P}{\rho_w g} \quad (4)$$

with $\Delta P = P_{water} - P_{air}$ the local pressure difference.

The sea water density is calculated using the UNESCO seawater equation of state (UNESCO, 1979), using measured temperature and constant salinity (37.5 PSU). Considering the natural variability of lagoon salinity (15 to 45 PSU), this implies a water level computational bias lower than 0.2 cm, which corresponds to the precision of the pressure measurements (Rey et al., 2020).

Level forcings

Apart from the wind, the water levels at the two sites are affected by different forcings.

In Berre lagoon, water level variations of the Mediterranean sea are transmitted through the Caronte channel. Large-scale sea level fluctuations due to atmospheric pressure systems are slow enough to be fully and uniformly transmitted within the Berre lagoon. At a smaller time-scale, the micro-tidal oscillations of the open sea level are observed to propagate within the lagoon. A typical tidal range of 20 cm is attenuated through the canal and is approximately equal to 5 cm within the lagoon. A tidal phase shift of 40 min is observed between the two stations and the result is a water level variation of 0.4 cm between the stations at a given time. Seiching oscillations have been observed at the Berre lagoon: the seiching period along the NW-SE axis is approximately 100 minutes and has a maximum amplitude of 8 cm (Paugam et al., 2020). The EDF hydroelectric power station released few liquid inflows during the study period, these discharges have a uniform impact on water level throughout the lagoon.

In Vaccarès lagoon, no tidal signal is observed within the lagoon due to very restricted SMM floodgates system and intermittent communication between the lagoon hydrosystem and the open sea. However, the lagoon water level can show significant variations due to several processes. Most importantly, the mean water level at Vaccarès is strongly controlled by evaporation and precipitation. It is estimated on the basis of historical data that the average annual precipitation is in the order of 600 mm/yr and the average annual evaporation 1500 mm/yr. The mean water level in the hydrosystem is also impacted by human interventions.

- The SMM floodgates system is used to control the salinity of the hydrosystem and to enhance biological exchanges. The degree of communication depends on the number of opened valves (up to 13) and on the opening duration which are empirically defined and not properly monitored. Overall, the exchanged fluxes being small and attenuated by the Imperial and Lion/Dame systems, the influence on the Vaccarès lagoon water level is slow and limited.
- Discharges of water from agricultural channels can also impact the lagoon level. No proper monitoring is available, but the inflows involved are small compared to the lagoon volume.

Each of the factors listed here can affect the Vaccarès lagoon water level, but the mass fluxes involved are low enough to drive a uniform action throughout the lagoon, i.e. they will not affect the 3h-averaged free surface slope calculation described below.

Water level measurement uncertainties

Here are summarized the different sources of errors regarding water level determination:

- Pressure transducer error: 0.2 cm;
- The use of a constant salinity for sea water density calculation: 0.2 cm;
- Tidal time shift in Berre lagoon between the two stations: 0.4 cm;
- Vertical positioning: 2 cm.

Considering the measurement and calculation biases mentioned above, the maximum error is approximately 2.8 cm in Berre lagoon and 2.4 cm in Vaccarès lagoon.

2.3. Data processing

To study the free surface tilting, the 3h-averaged water levels ζ at the south-east station (ζ_{SE}) and the north-west station (ζ_{NW}) are used for both sites. The 3hrs averaging time window was chosen as a compromise to be small enough to resolve the typical time scale of well-established wind events but long enough to remove the water level variations caused by seiching.

Wind tides are studied at both sites using the same method. The free surface tilting $\Delta\zeta$ is defined as the difference between ζ_{SE} and ζ_{NW} :

$$\Delta\zeta = \zeta_{SE} - \zeta_{NW} \quad (5)$$

The sign convention is therefore that if the north-west water level is lower than the south-east level, the free surface tilting will be positive which correspond to NW (mistral) wind events.

Assuming that both wind forcing and bathymetry are spatially uniform, the deformation of the free surface is assimilated to a linear slope S , simply calculated in practice using the water level difference $\Delta\zeta$ between two distinct measurement points separated by a distance L (equation 7).

The slope of the free surface is dimensionless but, for the sake of simplicity, it will be expressed in the following in *cm* (vertical) per *km* (horizontal). The distance L is defined along given reference axes (figure 3). In Vaccarès lagoon, the reference axis directly corresponds to the straight line between the 2 stations (figure 3.a), oriented at 123° True North: $L_{Vaccarès} = 7.2$ km. In Berre lagoon, the reference axis follows the long axis of the basin oriented at 140° (figure 3.b). The distance L is therefore calculated between the orthogonally-projected locations of Saint-Chamas and Le Jaï stations on the reference axis: $L_{Berre} = 18.7$ km.

Following Keulegan (1953) and Gillies (1959), the effective wind speed V_e , i.e. the projected wind component on the reference axis, is computed as follows

$$V_e = V \times \cos(\theta) \quad (6)$$

with V the raw wind speed and θ the angle between the wind direction and the reference axis. V_e is therefore positive in case of NW wind and negative for SE winds (figure 3).

The simplest approach used in the following analysis is to consider a constant C_D value at each site. It can be deduced combining equations 3 and 1 with the quadratic drag law of equation 2, a simple linear dependence is obtained between S and $\frac{V_e^2}{h}$

$$S = \alpha \frac{V_e^2}{h} \quad (7)$$

Figure 3: Determination of the effective wind speed V_e by projecting the wind component along Vaccarès (3.a) and Berre (3.b) lagoons reference axis

where the surface drag coefficient C_D can be inferred from the α regression coefficient as follows

$$C_D = \alpha g \frac{\rho_w}{\rho_a} \quad (8)$$

As mentioned in section 2.2.2, the mean water depth h is assumed to be spatially-uniform but may vary with time under the influence of a range of forcings. The spatial-uniformity assumption (i.e. assuming a flat horizontal bed) induces error in the C_D determination lower than 2% compared to the calculations performed assuming a linear sloping bed with the typical slopes for the two sites. The bottom elevation is defined as the averaged elevation along the transect throughout the reference axis of the lagoon. The time-varying water depth h is obtained, for each 3h-burst, by subtracting the fixed bed elevation from the spatially-averaged but time-varying free surface elevation $\langle \zeta \rangle = \frac{\zeta_{SE} + \zeta_{NW}}{2}$.

3. Results

3.1. Field conditions

Figures 4 and 5 show the time-evolution of the 3-hour average water levels of the two stations and associated wind speeds and wind directions at Marignane station and Tour-du-Valat station for Berre and Vaccarès lagoons respectively. A NW wind event is detailed on these figures for the two sites. Water level data from Carro station outside of Berre lagoon provided by HTM-NET network is also presented in figure 4, the station is located in figure 1.c. The span of the experiments ensured to cover a wide range of conditions at both lagoons, with several strong wind events in both main directions (NW and SE).

Fluctuations of the mean water level at the two sites shown in figures 4 and 5 suggest that in Vaccarès, the mean water level follows a seasonal trend, with higher/lower levels during winter/summer seasons. These seasonal fluctuations have been driven by the combination of various mechanisms described previously, but are not directly related to the wind forcing. Mean water level fluctuations are also observed in Berre lagoon but, in contrast with Vaccarès, the Berre lagoon water level is affected by day to week-scale fluctuations of the open sea level transmitted through

the Caronte channel. The semi-diurnal tidal oscillations are attenuated of about 75%. Longer water level fluctuations at Carro related to synoptic meteorological wind-pressure systems are also transmitted in the lagoon.

Recorded water level data near the lagoon boundaries reveal the expected wind tide dynamics: northwestern/southeastern water levels are lower during NW/SE wind conditions. The magnitude in water level difference between the stations increases with the wind speed.

Figure 4: Water levels (NGF referential) and wind data in Berre lagoon and Carro station from October 2019 to December 2019. Note that the complete dataset cover a longer period from March 2019 to August 2020. The right plots represent a 5-days mistral event.

3.2. Wind tides analysis

Figure 6 depicts the dependency of the surface slopes on effective wind speed for the two sites. The wind speed ranges are not perfectly symmetric at Berre, with stronger wind events being observed in NW wind conditions. The direct relationship between wind forcing and surface slope observed in figure 6 confirms that the wind is a major driver of mean surface slope in both systems. In weak wind conditions, slopes of the free surface are very low. Increase of wind speed induces a non-linear increase in the slope. For the same winds, the slope is higher in Vaccarès lagoon due to the shallower depth. Maximum values recorded for the two sites are summarized in table 3. Maximum observed slopes are 3.5 cm/km corresponding to a surge of 13 cm in Vaccarès lagoon and 2.2 cm/km corresponding to a surge of 20 cm in Berre lagoon. The slope development appears symmetric in case of NW or SE wind events: for a 10 m/s effective wind speed, the slope is approximately 2 cm/km in Vaccarès lagoon and 0.5 cm/km in Berre lagoon.

Overall, the orders of magnitude of observed slopes are in good agreement with existing modelling studies in the Berre (Leredde et al., 2002) and Vaccarès (Boutron et al., 2015) lagoons (table 1). The observed slope values are generally higher than most of the existing field observations (table 1), in relation with the shallow depths in Berre and Vaccarès lagoon. The only exception is

Figure 5: Water levels (NGF referential) and wind data in Vaccarès lagoon from October 2019 to January 2020. Note that the complete dataset cover a longer period from July 2019 to August 2020. The right chart represents a mistral event

the extreme value measured at Lake Okeechobee (Farrer, 1957) which associated a very long and shallow basin exposed to violent storm winds.

Studied site	Maximum slope during NW winds (cm/km)	Associated wind speed (m/s)	Maximum slope during S-E wind event (cm/km)	Associated wind speed (m/s)
Berre lagoon	2.4	20.4	0.8	14.4
Vaccarès lagoon	3.5	11.1	3.6	12.5

Table 3: Maximum surface slopes during NW and SE wind events and associated wind speeds

Figure 7 depicts the relationship between S and $\frac{V_e^2}{h}$. For both sites, the overall trend is well linear, which confirms the validity of the idealized approach assuming spatially uniform wind stress and depth. Coefficients of determination are high for both sites: $R_{Berre}^2 = 0.87$ and $R_{Vaccarès}^2 = 0.91$. Using a linear regression, values of α (equation 7) are determined: $\alpha_{Berre} = 2.45 \times 10^{-2}$ and $\alpha_{Vaccarès} = 3.12 \times 10^{-2}$. Related surface drag coefficients using equation 8 are $C_D = 2.01 \times 10^{-3}$ and $C_D = 2.56 \times 10^{-3}$ for Berre and Vaccarès lagoons, respectively. The possible causes for such a difference in surface drag coefficients are discussed later in Section 4.

Considering the quality of the linear regression, the idealized constant- C_D , i.e. wind-independent, approach provides rather robust orders of magnitude for wind tide prediction. The C_D wind dependency can be assessed by testing three well-known empirical wind-dependent C_D formulations against the present in-situ dataset.

First, Wu (1969) proposed equations 9 and 10 for low ($1 \text{ m.s}^{-1} < V < 15 \text{ m.s}^{-1}$) and strong wind ($V > 15 \text{ m.s}^{-1}$), respectively.

Figure 6: Measured surface slopes S versus effective wind speed V_e , the average is a solid line and the error margins are dotted lines. Berre and Vaccarès lagoon data are in red and blue dots, respectively.

$$C_D = 0.5V^{\frac{1}{2}} \times 10^{-3} \quad (9)$$

$$C_D = 2.6 \times 10^{-3} \quad (10)$$

The second formulation has been proposed by Garratt (1977) from observational data:

$$C_D = (0.75 + 0.067V) \times 10^{-3} \quad (11)$$

Thirdly, a study of wind trend and gustiness on sea drag made by Babanin and Makin (2008) in Lake George, Australia, enabled them to propose formulation 12.

$$C_D = 1.92 \times 10^{-7}V^3 + 9.6 \times 10^{-4} \quad (12)$$

Figure 8 and table 4 compare the predictive performances of the constant and three wind-dependent C_D formulations against the in-situ data. Root mean squared error (RMSE) and index of agreement (IA) (Willmott (1981)) are used to quantify the prediction errors in table 4

In Berre lagoon, slopes are correctly predicted using a constant C_D for wind speeds below 15 m.s^{-1} but are underestimated for higher wind speeds observed in NW conditions, similarly to the prediction from Garratt's wind-dependent formulation (equation 11). Such extreme wind conditions are better described by the equation 12 C_D formulation, but the latter shows a poorer prediction of medium winds, resulting in an overall larger error (table 4). The bimodal formu-

Figure 7: S versus $\frac{v_e^2}{h}$ in Berre (upper chart) and Vaccarès (bottom chart) lagoons. The in-situ data are points, the linear regressions are lines. R^2 , α and n are the linear determination coefficient, the linear slope and the number of data points.

lation proposed by Wu (1969) shows intermediate performance. In Vaccarès, each of the three wind-dependent formulations significantly underestimate the wind tide, resulting in much poorer predictions than the constant C_D approach (table 4). This result highlights the fragility of existing empirical wind-dependent formulations of surface drag coefficient, in particular when applied to very shallow lagoons. The depth-effect is therefore expected to not only directly affect the momentum balance, but also a range of surface processes affecting the drag.

C_D formulation used	Error	Berre lagoon	Vaccarès lagoon
Constant C_D	RMSE (m)	1.00×10^{-6}	1.97×10^{-6}
	IA	0.9251	0.9505
Wu (1969)	RMSE (m)	1.03×10^{-6}	2.86×10^{-6}
	IA	0.9167	0.8357
Garratt (1977)	RMSE (m)	1.05×10^{-6}	2.99×10^{-6}
	IA	0.8992	0.8109
Babanin and Makin (2008)	RMSE (m)	1.11×10^{-6}	3.24×10^{-6}
	IA	0.8824	0.7545

Table 4: RMSE and IA of measured and predicted slopes using a constant value of C_D and wind-dependent C_D values from the literature in the two studied sites.

4. Discussion

The present research work has provided a detailed field database on wind-induced free surface tilting, the so-called wind tides, in two shallow semi-enclosed basins. The measurements first confirmed the expected main trend: the higher the wind speed, the steeper the free surface slope. In addition, a significant effect of depth is observed, with greater surface tilting in the shallower lagoon. From these observations, the 1-D steady depth-averaged momentum balance was used to estimate the surface friction coefficient based on the assumptions of a flat horizontal bed and a spatially-uniform wind stress. The data analysis confirmed the robustness of such a simple approach in the present context. However, the parameterization of the surface drag coefficient remains a tricky issue. The existing wind-dependent parameterizations provided satisfactory agreement at the deeper site but showed systematic underestimations of the wind tide at the shallower site. A simple constant C_D provided slightly better performance, but required to use different values for different depths. These observations suggested that additional physical parameters should be taken into account for the drag coefficient parameterization in very shallow lagoons. To provide further insight on the wind tide physics, discussion points are organised in four main topics: the wave field, the sloping bathymetry, the wind unsteadiness and the currents.

4.1. Wave field

The sea state influence on surface drag has been widely studied, mainly in the context of open ocean and moderate wind speed. Air-sea interactions are very complex at small scales because multiple mechanisms affect sea drag simultaneously (Babanin and Makin, 2008). The effect of the wave field structure on surface drag can be accounted for through wave age (Janssen, 1989; Donelan, 1982; Donelan et al., 1993; Uz et al., 2002; Young and Verhagen, 1996; Smith et al., 1992; Babanin and Makin, 2008; Kudryavtsev et al., 2014; Stewart, 1974; Oost, 1998; Oost et al., 2002) or wave steepness parameters (Hsu, 1974; Taylor and Yelland, 2001). Studies have shown that the drag coefficient value is higher in windy seas, with short and steep waves, than in fully developed seas associated with longer waves (Young and Verhagen, 1996; Smith et al., 1992; Babanin and Makin, 2008; Kudryavtsev et al., 2014; Uz et al., 2002). This effect should be accounted for in enclosed basins, where limited fetch conditions will affect the wind stress: short basins are expected to show higher wind stress and drag coefficient.

The sea state is also strongly affected by the depth. Similarly to short fetch, a finite depth will increase surface drag compared to open ocean by inhibiting the development of long waves (Smith et al., 1992; Kudryavtsev and Makin, 2004; Babanin and Makin, 2008). In deep water condition, the wave age is defined as the ratio between the wind speed and the wave celerity. The celerity (c) increases with the period (T) of the waves : $c = 1.56 \times T$. Waves are considered to reach their maximum period (unlimited fetch) when their speed is approximately equal to the wind speed. By contrast, waves in shallow water conditions are non-dispersive, i.e. the limit of speed of the waves is $c = \sqrt{gh}$ regardless of their frequency and therefore waves do not necessarily reach the wind speed. This results in a depth-control of the wave field favoring shorter waves in shallow water.

Both shorter and shallower basins are therefore associated to shorter wave spectra, expected to enhance the surface drag. This latter mechanism has been confirmed in laboratory experiments, where reduction of the short wind-wave spectra caused a decrease of the wind stress by as much as 20-30% at a given wind speed (Uz et al., 2002). Taken together, these observations are in line with our observation of a higher drag coefficient for the shallower and shorter lagoon (Vaccarès lagoon).

4.2. Sloping bathymetry

By contrast to most studies performed in unidirectional wind conditions, our sites are exposed to two opposite wind directions. Such configuration allowed to question the role played by a sloping bathymetry on the wind tide amplitude, in direct connection with the previous analysis of depth effect.

Figure 9 depicts C_D boxplot diagrams for Vaccarès lagoon. The presented data is focused on significant wind events, with wind speed greater than 5 m.s^{-1} , and separated into NW (left panel) and SE (right panel) wind directions. For great depths, the surface drag coefficients are in the same range for both wind directions. By contrast, for low depths (less than 1.5 m), a measurable difference is observed, with C_D in SE wind conditions being higher than in NW wind conditions by about 30 %. While finer data and/or a wave propagation model would be necessary to provide a comprehensive description of the involved physics, the hypothesis can be raised that, for a given average depth over the studied transect, the bottom slope may play a role in the wave development. In SE wind conditions, the depth decreases along the fetch, forcing the wave

to propagate in shallower conditions, therefore limiting the spectrum development toward lower frequencies, constraining the propagation speed and finally resulting in higher surface drag. By contrast, in NW wind conditions, the depth increases along the fetch, allowing the waves to get longer and to propagate faster, resulting in a relatively lower surface drag than in the opposite wind direction. This effect can be assumed to be stronger at the lowest depths where the bottom slope induces stronger relative variation of depth along the transect. This explains that the difference in C_D in opposite wind direction is only observed for the lower recorded depths in figure 9. It should be borne in mind that this bottom slope effect on C_D strictly relates to a modification of the wave field development while the direct bottom slope effect on the momentum balance remains very slight in the present context, as discussed in Section 2.3.

Figure 9: Boxplot of C_D versus the water column in Vaccarès lagoon in case of NW wind events (left chart) and SE wind events (right chart). Red lines represent medians, blue polygons contain 25-75% of the data, dashed line boundaries contain 10-90% of the data, and red crosses represent extreme points.

4.3. Wind unsteadiness

Wind gusts are generally expected to affect the drag coefficient : high drag coefficients occurs when conditions are strongly non-stationary (Drennan et al., 1999; Babanin and Makin, 2008). Uz et al. (2002) and Kudryavtsev and Makin (2004) highlighted that when the wind forcing is modulated in time, the wind stress tends to be higher under decreasing wind than under increasing wind

at a given wind speed. These processes are mainly related to the delayed response of short wind-wave spectra to varying wind forcing. In the present study, no effect of wind gusts on the wind tide were identified. Further experiments with local and high frequency wind and wave measurements are required to better understand the surface drag response to wind unsteadiness.

4.4. Currents

The simplified depth-averaged momentum balance equation used for the present analysis ignores the potential effect of currents on wind tide development. In realistic configurations, the wind stress at the water surface drives a complex three-dimensional balance between free surface slope related to barotropic pressure gradients and a variety of horizontal and vertical circulations depending on the basin morphology and boundary conditions (Csanady, 1973; Orlić et al., 1994), not to mention baroclinic effects. In shallow water, the bottom stress can significantly contribute to the momentum balance, with an increasing effect in shallowing depth or rough bed conditions (Tickner, 1957). Keeping our idealized 1D depth-averaged approach, a first estimate can be provided by introducing an additional term for bottom friction $\tau_b/\rho_w g h$ in equation 1. This term is usually quadratic: $\tau_b = \rho_w C_b U^2$ where C_b is the bottom friction and U the current velocity. Typical orders of magnitude for U can be extracted from the numerical studies performed in Vaccarès (Millet et al., 2010) and Berre lagoons (Alekseenko et al., 2013). In Vaccarès lagoon, a current of 0.08 m/s was predicted during a 8 m/s NW wind event while for Berre lagoon, a 20 m/s NW wind event led to a mean current of 0.12 m/s. Considering a classical value for bottom friction of 0.002 for a smooth sandy bottom (Hsiao S. V. and Shemdin O. H., 1978), the bottom friction term is expected to contribute less than 3% of the free surface slope in Vaccarès/Berre lagoons. This confirms the validity of the initial assumption of a negligible effect of current on wind tide in the present context. A more comprehensive knowledge of the full 3D wind-induced circulation system will be necessary to assess more precisely the role of bottom friction and circulation patterns on the wind tide dynamics (De Marchis et al., 2012).

5. Conclusions

Wind tides are responsible for water level variations and can lead to damaging flooding in low-lying areas. The wind effect is greater in semi-enclosed or enclosed basins and further amplified at shallow depth. The present study is based on a long-term survey of water levels in two shallow coastal lagoons located in the eastern part of the Gulf of Lion, France: Berre lagoon and Vaccarès lagoon. The two field sites were selected owing to their similar wind exposure but different morphology and bathymetry. A wide range of wind conditions have been encountered, reaching up to 20 $m.s^{-1}$. The free surface tilting was studied using two stations deployed along the main axis of the wind forcing.

The observations showed the expected trend: the higher the wind speed, the steeper the free surface slope. They also confirmed that, in shallow lagoon, the 1-D steady depth-averaged momentum balance provides a very satisfactory description of the involved physics. However, the parameterization of the surface drag coefficient C_D remains an unresolved issue. Existing wind-dependent parameterization of C_D provided drastic underestimations of the wind tides, up to a factor three for our shallower site. These findings emphasize the need for a better understanding of the depth-effect on wave development in finite depth and consequently on the surface drag coefficient prediction.

By contrast, the role played by wind gustiness and water circulation on the wind tide amplitude appeared to be negligible compared to wind and depth effects.

Future research work is planned at both sites, with high-resolution high-frequency measurements of water levels and currents with the aim of better understanding the wind tide dynamics. Particular attention will be paid on wave field development and the related surface drag coefficient together with the 3D circulation patterns aiming to characterize more finely their contribution in the momentum balance in shallow lagoons, in order finally to improve our ability to predict wind tides.

Acknowledgments

HTM-NET observational network has received recurrent co-financing since 2013 from CNRS/INSU for the national program SOERE, from ILICO-DYNALIT and also from the Toulon Provence Méditerranée (TPM) urban community.

Météo-France is thanked for providing the wind data at the Tour-du-Valat and Marignane meteorological stations.

The support is acknowledged of the Departmental Council of the Bouches-du-Rhône (CD13) for station siting permits, SHOM for their collaboration, Tathy Missamou and Jean-Luc Fuda from the Mediterranean Institute of Oceanography (MIO) for the installation and the maintenance of the stations, Didier Mallarino from the OSU Pythéas institute for the HTM-NET website maintenance and Météo-France for meteorological data.

The Tour-du-Valat foundation and the Camargue National Nature Reserve are acknowledged for their help in installing and maintaining the Vaccarès lagoon stations.
