and N. Ouazzani

ABSTRACT

Membrane bioreactor (MBR) has been proven to be an efficient technology capable of treating various industrial effluents. However, the evaluation of its performances in the case of olive mill wastewater (OMW) over a conventional activated sludge (CAS) have not been determined yet. The present study aims to compare OMW treatment in two laboratory scale pilots: an external ceramic MBR and CAS starting with an acclimation step in both reactors by raising OMW concentration progressively. After the acclimation step, the reactors received OMW at 2 g_{COD}/L with respect to an organic loading rate of 0.2 and 0.3 kg_{COD}/kg_{MLVSS}/d for MBR and CAS, respectively. Biomass acclimation occurred successfully in both systems; however, the MBR tolerated more OMW toxicity than CAS as the MBR always maintained an effluent with a better quality. At a stable state, a higher reduction of 95% chemical oxygen demand (COD) was obtained with MBR compared to CAS (86%), but both succeeded in polyphenols removal (80%). Moreover, a higher MLSS elimination from the MBR treated water (97%) was measured against 88% for CAS. Therefore, CAS was suitable for OMW treatment and MBR could be proposed as an alternative to CAS when a better quality of treated water is required.

Key words | acclimation, aerobic treatment, COD and phenolic compounds removal, conventional activated sludge process, external ceramic membrane bioreactor, olive mill wastewater

HIGHLIGHTS

- Olive mill wastewater (OMW) treatment by membrane bioreactor (MBR) and activated sludge (AS) were compared.
- Biomass acclimation and polyphenols degradation occurred successfully in both systems.
- At 0.2 and 0.3 kgCOD/kgMLVSS/d, MBR showed higher efficiency at 95% than CAS (86%).
- MBR showed better performances (95%) than CAS (86%) for OMW COD treatment.
- Considering the Moroccan situation, the CAS could be more adapted for OMW treatment.

INTRODUCTION

Olive oil production is one of the main agro-industries in Mediterranean countries and the production of olive oil is increasing due to the nutritional benefits and economic interest of this substance. However, the activity generates significant amounts of olive mill wastewater (OMW), which represents a serious environmental problem in

many producing countries. The OMW volume produced during the process varied from 40 to 60 L for pressing method and it ranged from 100 to 120 L for triple phase centrifugation method per 100 kg of olives (Rahmani 2010). The OMW is one of the most contaminant effluent for the environment. The 5-day biochemical oxygen demand

(BOD₅) values are between 12 and 63 g/L and chemical oxygen demand (COD) values are between 80 and 200 g/L. These concentrations are around 200–400 times higher than those measured in typical municipal sewage. In addition, OMW contains phenolic compounds which are recognized with phytotoxic and antimicrobial properties.

Several methods are being used for the treatment of OMW such as electrochemical oxidation, stabilization ponds, thermal concentration, and other physicochemical treatments (Paraskeva & Diamadopoulos 2006). However, most methods are expensive and produce sludge and other secondary by-products which need to be further treated. The aerobic methods are recognized as economic alternatives to physicochemical methods for the treatment of a wide range of wastewater effluents. In most cases, conventional activated sludge (CAS) is used and preferred for large-scale application (Sipma *et al.* 2010). However, the feeding of this system by highly toxic OMW could be harmful and disturbing for its normal functioning. The inhibition of the biodegradation might occur because of the proper toxicity of OMW phenolic compounds towards microorganisms (Esmail *et al.* 2015).

The membrane bioreactor (MBR) has attracted attention concerning its high ability for the removal of a large type of contaminants including phenolic compounds (Baresel *et al.* 2019). The integrated membrane in the MBR replaces the clarifier in CAS process with settling ability problems. The MBR treatment of industrial wastewater has become attractive for the robustness of the process to treat high organic load and inhibitory compounds (Fazal *et al.* 2015). The main problem associated with MBR process is membrane fouling, therefore, it has to be managed in order to guarantee the development of a sustainable process. Soluble microbial products (SMP) are currently considered as the main part of extra polymeric substances (EPS) which are responsible for membrane fouling. Due to the lack of information about the

characteristics of SMP in MBR and CAS treating OMW, one of the main objectives of this study is to assess the feature and appearance of SMP in both reactors and to link their production to the operating conditions. The treatment of OMW in MBR was successfully performed in previous studies with a preliminary acclimation step. The COD and phenolic compounds removals in the range of 80–95% and 80–90% were respectively reached (Dhaouadi & Marrot 2008; Jaouad *et al.* 2018). As the effluent treatment with MBR was reported to be more expensive than CAS treatment (Bertanza *et al.* 2017), the objective of the current study is to investigate and compare the performances of two pilots, MBR and CAS, operating simultaneously for the treatment of OMW. The COD and phenolic compounds removal efficiencies and the quality of the treated water were principally assessed during the running of both pilots. A strategy of OMW treatment in Morocco was then proposed. The purpose of this strategy is to demonstrate which one of the reactors is effective in OMW wastewater treatment considering the Moroccan context.

MATERIALS AND METHODS

MBR and CAS pilots set up

A laboratory scale MBR system (30 L) (Polymem, France) was used in this study. The membrane was placed outside of the bioreactor and operated under a cross flow velocity of 4 m/s to reduce membrane blockage. Diagrams of the pilot plants are presented in Figure 1.

The aerobic tank was supplied by 30 L activated sludge and the aeration was provided by small bubble diffusers (6–8 mgO₂/L). Recirculation of activated sludge from the aeration tank to the membrane was accomplished by recirculation pump. The temperature was maintained at 25 °C

Figure 1 | Schematic diagram of MBR (a) and CAS (b) installations.

inside the bioreactor using a cooling coil system. Initially, the experiment was conducted by an ultrafiltration (UF) membrane to retain specific enzymes involved in phenolic compounds removal. Afterwards, the UF membrane was replaced by a microfiltration (MF) membrane to guarantee a constant flow rate of the permeate with less membrane fouling. Both of the used membranes (UF and MF) were tubular mono-channel ceramic types (Novasep-Orelis, France) with an effective filtration area of 0.02 m², initial water permeability of 100 L/h/m²/bar. The pore size of UF membrane was 150 kDa while it was 0.1 µm for the MF membrane. Transmembrane pressure (TMP) increase was controlled with two manometers set at the inlet and outlet of membrane module (alimentation and retentate). Both permeate and feed flows were kept constant at 0.75 L/h.

The second reactor was a pilot-scale automated activated sludge plant (TAE/3000) (Figure 1(b)). The pilot is composed of three tanks: feed wastewater tank (100 L), aerobic tank with a working volume of 60 L and containing flocculated activated sludge. The settling tank (30 L) is the final module where the flocculated activated sludge is separated from the treated water. A part of sludge in the settling tank was regularly recirculated into the bioreactor to ensure the presence of a significant biomass amount inside the biological reactor. Ambient temperature was maintained at approximately 25 °C. In the aeration tank, the oxygen was provided by an air pump and diffused inside the bioreactor using a large diffuser at a concentration of 2–3 mgO₂/L.

Operating conditions

Initially, the pilots were filled with activated sludge. In the case of MBR, the activated sludge was supplied from a submerged MBR treating municipal wastewater of the village Le Rousset (France, 12,000 inhabitants equivalent, 1,800 m³/d flow rate, organic load 0.1 kg_{BOD5}/kg_{MLVSS}/d). For the CAS plant, the biomass was taken from a full-scale municipal wastewater treatment (WWTP-AS) of Marrakesh (Morocco, 1,300,000 inhabitants equivalent, 120,000 m³/d flow rate). Initial mixed liquor suspended solids (MLSS) concentrations were around 4 g_{MLSS}/L for CAS and 8 g_{MLSS}/L for MBR process. Then, the biomass was pre-adapted in both pilots to a synthetic substrate containing glucose as carbon source: C₆H₁₂O₆ (2.1 g/g_{MLVSS}), KH₂PO₄ (0.2 g/g_{MLVSS}), NaHCO₃ (0.3 g/g_{MLVSS}), MgSO₄ (0.1 g/g_{MLVSS}) and CaCl₂ (0.02 g/g_{MLVSS}). Afterwards, the biomass was acclimated to gradual concentrations of OMW following the acclimation procedure described by Jaouad *et al.* (2016). During the acclimation step, the food

to microorganism ratio (F/M) was kept around 0.3 kg_{COD}/kg_{MLVSS}/d with a starting ratio of 20% OMW/ 80% glucose (v/v). Then the volume of OMW increased progressively as the biomass growth was noticed for several days.

Based on the finding from Jaouad *et al.* (2016), the maximum biomass growth (1.8/d) can be obtained with OMW using a COD concentration of 2 g_{COD}/L and tended to decline after further augmentation of OMW concentration (superior to 2 g_{COD}/L). Therefore, at the end of the acclimation step, the dilution of the raw OMW effluent until 2 g_{COD}/L was necessary to avoid substrate inhibition effect. The acclimation phase was performed under an infinite sludge retention time (SRT) for both reactors and different hydraulic retention time (HRT) of 16 h for AS and 24 h for MBR. At steady state, for the microfiltration step (MF-MBR), the F/M ratio and the mixed liquor volatile suspended solid (MLVSS) were fixed at 0.2 kg_{COD}/kg_{MLVSS}/d and 8 g/L, respectively. The MBR alimentation was done continuously with a constant OMW loading, previously pre-filtered (cut off of 200 µm). In addition, a daily purge was performed in order to keep a constant value of MLVSS concentration of 8 g/L in the MBR and to minimize membrane fouling. For the CAS pilot, the bioreactor was fed only by OMW at a fixed F/M ratio of 0.3 kg_{COD}/kg_{MLVSS}/d. In addition, a frequent purge was performed to maintain 4 to 5 g_{MLVSS}/L in the CAS bioreactor and to ensure a high water clarification. The stabilization of the system was obtained a few days later. The SRT were fixed at 20–25 days for both pilots.

The OMWs used in this experience were sampled at two different periods (in 2013 for OMW1 and in 2014 for OMW2) from a discontinuous extraction unit from Marrakesh, southern Morocco (Table 1). To obtain comparable results, the alimentation of the two pilot plants by OMWs was performed using similar F/M ratio of 0.3 kg_{COD}/kg_{MLVSS}/d.

Table 1 | Physical and chemical composition of OMW1 and OMW2

Parameters	OMW1 (MBR)	OMW2 (CAS)
pH (25 °C)	5	4.1
Conductivity (mS/cm)	9.3	16
Total suspended solids (TSS) (g/L)	2.1 ± 0.3	4.5 ± 0.2
COD (g/L)	96 ± 2	170 ± 5
Total nitrogen (TN) (g/L)	0.46	2.6 ± 0.1
Total phosphorus (TP) (g/L)	0.1 ± 0.03	0.3 ± 0.02
Total polyphenols (g/L)	3.2 ± 0.01	8.1 ± 0.4
Proteins (g/L)	0.04	0.004

Analytical methods

For both pilots, samples were taken from the influent, bioreactor and the outlet to perform various analysis. Activated sludge was taken from the aeration reactor and centrifuged at 4,000 g for 15 min to separate suspended solids from the supernatant; the measure of mixed liquor suspended solids (MLSS) was obtained by drying solid residues in a stove at 105 °C for 24 h. The MLVSS content was determined by placing the dried solid residues in an oven at 550 °C for 2 h. These MLSS and MLVSS were measured daily to evaluate the biomass growth in both systems. The COD and phenolic compounds content was assessed twice a week by colorimetric methods to assess their removal rates. The TMP was measured to monitor the filtration performances and membrane fouling. Once the TMP reached high values (>1.2 to 1.5), a chemical cleaning of the membrane was applied to restore initial values of TMP and a constant permeate flow of 0.75 L/h. In addition, the total MLSS in the outlet of both pilots was determined to evaluate the quality of the final water obtained over the treatments. The monitoring of sludge volume index (SVI) was performed periodically to evaluate the quality of sludge settleability over time. The polysaccharide fraction of SMP was determined by the phenol sulfuric acid method, as described by Dubois *et al.* (1956). Moreover, the method developed by Frolund *et al.* (1995) was applied to determine the proteins and humic fractions of SMP content.

RESULTS AND DISCUSSION

Evolution of the biomass

The evolution of MLSS, MLVSS and F/M ratio during the operation of MBR and CAS pilots is given in Figure 2.

This figure illustrates an increase in the biomass content gradually with the rise of OMW concentration with time, proving that the acclimation step was successfully performed in both reactors. In the MBR, the MLVSS content increased and reached the high concentration of 10 g/L at a ratio of 40% OMW/60% glucose. The 150 kDa UF was used in the initial acclimation step to retain enzymes involved in phenolic compounds removal. However, with the increase of OMW ratio to 60% OMW/40% glucose (day 51), a brutal decrease of MLVSS concentration occurred. At the same time, the MLSS concentration stayed around 10 g/L. It seems that the biomass is under remarkably high toxicity conditions. This could be related

to an effective presence of highly toxic phenolic compounds inside the bioreactor which was set up by the small size of the pore (150 kDa UF). A rearrangement of organic matter from OMW, in particular phenolic compounds with bacterial flocs and SMP could be responsible for the rapid increase of biomass instability and death. Then, the UF was replaced by an MF membrane in order to limit the toxic OMW molecules' accumulation inside the MBR. Similar to the MBR, the MLVSS content in CAS increased in parallel with the injection of new doses of OMW, which shows a good biomass adaptation to this toxic effluent. The MLVSS content for CAS pilot reached a concentration of 4.3 g/L at 90% of OMW as mass ratio. After the increase of OMW concentration in CAS to 100% at day 55, the biomass content remained high and stable, showing the adaptation of biomass to this harsh environment. Concerning the MBR, with the change of UF by an MF and despite feeding the bioreactor by OMW only, the biomass continued to increase to reach 20 g_{MLVSS}/L.

The steady state was reached at day 110 for MBR at an F/M ratio of 0.2 kg_{COD}/kg_{MLVSS}/d and MLVSS of 8 g_{MLVSS}/L while for the CAS the system stabilization was obtained at day 55 at a fixed MLVSS of 5 g_{MLVSS}/L and a F/M ratio of 0.3 kg_{COD}/kg_{MLVSS}/d.

Treatment performances

COD removal. Figure 3 represents the performance of MBR and CAS reactors for the COD removal during time. During the first step of acclimation, until a ratio of 40% OMW, the MBR showed a higher elimination of COD (95%) than CAS (86%).

Afterwards, with the increase of OMW mass ratio to 60% in the MBR, an accumulation of COD in the bioreactor was observed throughout the experiment. However, the MBR kept a high COD removal (95%) and a good permeate quality. This result could be explained by the presence of a membrane that retained the pollutants and kept the water free of them even if biological fluctuation occurred. However, in the case of CAS, the increase of OMW mass ratio (between 40% and 90%) involved highly stressful conditions inside the bioreactor reflected by a slight decrease of COD removal to 80%. The harsh atmosphere inside the bioreactor affected the biomass biodegradation efficiency and the clarification efficiency as well. However, at day 55 the COD removal efficiency reached again an optimal value of 86% at the same time of the biomass adaptation. It appeared from these results that the MBR has more abilities to produce constantly a highly treated water than CAS and

Figure 2 | Evolution of MLVSS, MLSS and F/M ratio during time for MBR (a) and CAS (b).

limits biological disturbance inside the bioreactor. The UF was then replaced by an MF membrane. That way, the bioreactor allowed to eliminate compounds with sizes ranging between 150 kDa and 0.1 μm that accumulated.

After the application of MF, at the stable state, the biomass showed high activity towards OMW pollutants removal. The MBR performance was noticeable and the removal of COD reached the high value of 95% while it not exceeded 86% for CAS. Furthermore, the MBR delivered an effluent with lower COD concentration (0.107 g/L) than

CAS (0.152 g/L) which complies largely with the limits fixed by the Moroccan Standards for Wastewater Discharge (0.120 g/L) ([Moroccan Standards for Wastewater Discharge 2013](#)). The MBR was able to achieve a higher elimination of COD compared to CAS. The greater elimination of organics by the MBR was due to the presence of a MF membrane, which worked in synergy with the biomass for a better biodegradation of OMW.

The performance of CAS and MBR in this study for the treatment of OMW was compared to the efficiencies of

Figure 3 | COD removal and COD concentrations in substrate, MBR supernatant and permeate as a function of time for MBR (a) and CAS (b).

Table 2 | COD and phenol removals for OMW treatment with different processes

Process	Type of treatment (single or combined)	COD inlet (g/L)	COD removal (%)	Phenol removal (%)	Reference
AS	Single	1.1	86	82	This study
MBR	Combined (AS/microfiltration)	1.6	95	80	
Photocatalytic	Combined (Anaerobic fermentation/ TiO ₂ -PAC)	1.9	58	-	Baransi <i>et al.</i> (2012)
Electrocoagulation	Combined (UF/EC)	1.1	78	-	Yahiaoui <i>et al.</i> (2011)
AS	Combined (UASB/AS)	0.6	60	-	Gizgis <i>et al.</i> (2006)
UASB	Single	2.8	93	-	Ergüder <i>et al.</i> (2000)
SBR	Combined (GAC/SBR)	1.3	40	-	Farabegoli <i>et al.</i> (2012)
Biofilters	Combined (UF/NF/RO/Biofiltration)	1.2	63	-	Stoller <i>et al.</i> (2016)

other advanced technologies. As noticed in Table 2, MBR appears to achieve the highest COD removal (95%) compared to the last stages of the other combined treatment processes (Anaerobic fermentation/TiO₂-PAC; UF/EC; UASB/AS; GAC/SBR; UF/NF/RO/Biofiltration). The presence of MF membrane acted as a solid physical barrier for better wastewater impurities retention and therefore obtaining a better treated water compared to the other combined processes. Even if the CAS performance to treat OMW (86%) was much lower than MBR, it obviously showed from Table 2 that the process achieved higher COD elimination compared to the two other studies using the aerobic biodegradation as a last stage in the combined treatment (UASB/AS; GAC/SBR). The higher COD removal rate could be attributed to the acclimation protocol performed in this study which allowed the best treatment profile for CAS.

Polyphenol removal. The performance of MBR and CAS for the removal of phenolic compounds during the operation time is presented in Figure 4. During the acclimation step, at low OMW concentrations (20–40% mass ratio) feeding the bioreactor, the MBR showed an acceptable elimination of phenolic compounds (65%) against 54% for CAS.

This result could be explained by the fact that in the MBR the biomass content was greater (8 g/L) than in CAS (4 g/L). At the same time, the MBR biomass was constituted of flocs with a smaller size (35 μ m) than CAS (150 μ m). This implied that with the decrease of flocs size, the flocs exchange surface has increased in the case of MBR and the adsorption of the phenolics compounds has increased as well. When OMW mass ratio increased to 60%, an accumulation of phenolic compounds was noticed which seems caused by the very low fine pore size of UF membrane

Figure 4 | Phenolic compounds removal and phenolic compounds concentrations in substrate and permeate as a function of time for MBR (a) and CAS (b).

(150 kDa). However, the removal of phenolic compounds remained acceptable at 65%. The UF membrane was then replaced by an MF membrane in order to get rid of the phenolic compounds accumulated inside the bioreactor. For CAS, the phenolic compounds removal improved during the operation time from 54% to 80%. This result shows the gradual adaptation of the biomass to OMW toxicity during the acclimation period leading to an effective elimination of these compounds in the CAS bioreactor. During the last period of acclimation, both reactors were fed totally with OMW. At stable state, the elimination of phenolic compounds was fixed at around 80% for both reactors.

Hydraulic performances. Figure 5 illustrates the evolution of SVI for CAS treatment and TMP as well as permeate flux during the functioning of MBR. The monitoring of these parameters was in order to compare the performance and the extent to which these two plants can produce a treated

water with a high quality together with the influence of hydrodynamic conditions fixed over both experiments on flocs decantability in CAS or on membrane fouling in MBR.

In the case of MBR, during the acclimation period the TMP has known a frequent increase simultaneously with the introduction of OMW in a new higher concentration leading to significant membrane fouling occurrence over time. On the other side, the quality of water clarification remained good as confirmed by the high COD removal efficiency obtained (95%). As can be seen, the low cut off of UF membrane was appropriate to obtain an effluent with a high quality; however, this membrane seems to be responsible for the rapid, easy and frequent membrane fouling appearance. The UF has influenced indirectly the accumulation of molecules with high molecular weight in the bioreactor supernatant over the progressive introduction of OMW in a new higher concentration and, hence, their contribution on membrane fouling. Furthermore, the very low pore size of UF has permitted a rearrangement between sludge flocs,

Figure 5 | Evolution of TMP for MBR (a) and SVI for CAS (b).

SMP and OMW compounds, which participated greatly in membrane fouling. Then, the UF was replaced by an MF membrane (0.1 μm).

The monitoring of SVI parameter was performed during the operation time of CAS since it gives a direct measurement of the sludge settling quality. Figure 5 illustrates that from the start up of the acclimation to 60% OMW mass ratio feeding the bioreactor, it was noticed that the SVI had not varied too much and the values measured were maintained at around 120 mL/g, indicating healthy sludge settling. Even if the SVI was good, the removal of COD revealed several slight drops (10%) while increasing OMW ratio had revealed unstable water clarification over time. The disturbance of biomass activity had directly affected the sludge settling quality contrary to MBR. The coupled membrane with this reactor played a physical barrier to biomass disaggregation in stress periods which did not affect the water clarification quality. From 60% to 90% OMW mass ratio used for the CAS treatment, the SVI decreased slightly to 97 mL/g but still indicated good sludge settling ability. The measured value remained comparable to values obtained by Diez *et al.* (2002) (55–112 mL/g) who treated bleached kraft paper using an activated sludge system.

At stable state in the MBR, the membrane filtration was effective and the fouling was easily managed due to favorable hydraulic conditions of external ceramic MBR. Furthermore, the treatment in the MBR was effective.

The use of MF had a great potential for water clarification resulting in a highly clear effluent reaching a rate of MLSS elimination lower than 5 mg/L and a turbidity removal of 98%. In the case of CAS, the SVI increased noticeably and was maintained around 136–150 mL/g. According to Shahzad *et al.* (2015) the obtained values of SVI still reveal an acceptable biomass settling; however, the values above 150 mL/g demonstrate poor settling ability. For the CAS performance, the removal of MLSS reached a rate of 88% with MLSS concentration in the outlet of 30 mg/L. The results showed clearly that the MBR was capable of providing an effluent with a better quality than CAS.

Composition of SMP and properties. Figure 6 presents the evolution of proteins, polysaccharides and humic substances concentrations over time in MBR and CAS pilots. Proteins, polysaccharides and humic substances are quantified as the main SMP components.

During the acclimation period for the MBR, the results showed an increase of SMP concentration (i.e. proteins and polysaccharides) in the bioreactor simultaneously with the

introduction of new OMW doses (at day 31 and from day 38 to day 45 and at day 53). In the case of CAS, the SMP increase (i.e. proteins) in the bioreactor was visible over time with the two relatively high OMW concentrations applied (at days 13 and 27). This surge of SMP is likely due to the high response of the microorganisms to the effluent augmentation in order to assure their self-defense and protection against the toxic conditions of the environment they existed in. However, in MBR, the membrane fouling propensity increased as these SMP were produced. The UF membrane (150 kDa) retained a part of SMP and OMW components, promoted their deposition greatly on its surface. In CAS, the production of SMP has not affected badly the quality of sludge flocculation and its settling ability. Proteins are the main fraction of the SMP produced. The presence of this fraction participates in the formation of strong bonds between biomass cells resulting in good flocs flocculation and the occurrence of a healthy water clarification (Avela Vasquez 2010). The low presence of these substances in the settling tank (4 mg/L) compared to supernatant bioreactor (13 mg/L) confirmed their active implication in the flocs formation and robustness. Afterwards, at steady state in the MBR the concentration of SMP fractions was stable at a low level. The SMP proteins and polysaccharides were retained effectively by MF at 74% and 92%, respectively, while in the case of applying UF membrane, the retention of these components was around 50% and 65%. In regard to MBR set up, Villain-Gambier *et al.* (2019) obtained similar results and showed in their experience that SMP retention rate highly decreased under stressful conditions compared to the normal conditions applied. These authors noticed that under stressful conditions consisting of the decrease of F/M ratio, a drop of the biomass of 11% was observed and an increase of SMP production. This SMP was mainly composed of proteins fraction with low molecular weight components of 400, 200 and 20 kDa and which has contributed drastically to the membrane fouling. The membrane was regularly fouled during acclimation step (four times) requiring the process to stop and chemical cleaning whereas fouling was more progressive at a stable state. It seems that during the first period with UF membrane, a higher amount of SMP compounds were produced and participated in the membrane fouling. For the CAS treatment, at a stable state the amount of SMP substances was the same in the bioreactor supernatant and settling tank except for the SMP proteins where their amount was slightly lower in the settling tank (2 mg/L) than in the bioreactor supernatant (4 mg/L).

Figure 6 | Evolution of SMP production during time in MBR and CAS pilots: polysaccharides (a₁, b₁) proteins (a₂, b₂) and humic substances (a₃, b₃).

Figure 7 illustrates the SMP concentrations at a stable state in CAS and MBR pilots. The results revealed that a great part of SMP substances noted inside both bioreactors came from the influents used. Nevertheless, the influent feeding the MBR contained higher SMP concentrations compared to the effluent feeding CAS. This shows obviously that SMP production in both bioreactors was not all related to biomass release but it came from OMW influents. Moreover, the content of humic substances and polysaccharides knew a higher decrease in the biological reactors of CAS and MBR compared to their initial content in OMW influents. This decrease could be the result of various phenomenon such as their sorption on bioflocs, their participation to bound EPS or their elimination by sludge waste (Villain *et al.* 2014).

Strategy of OMW treatment in Morocco. Morocco is one of the Mediterranean countries concerned with a massive production of olive oil, with an annual production capacity of 2 million tons of olives and is the fourth largest producer of olives according to the agriculture ministry report of 2018.

In Marrakesh-Safi region, the olive oil industry produced about 305,000 tons per year of olives and a quantity of oil of 40,000 tons per year. In addition, the annual volume of OMW produced in this region is estimated at 152,500 m³/year.

Several valorization methods have been suggested for OMW including bioconversion of oil mill wastes to bio-energy and biomolecules production, OMW field spreading and OMW application as biopesticides. The other option consisted of OMW biodegradation, using aerobic technologies. At large scale, the activated sludge

process remains the most practical way for wastewater treatment. Nevertheless, the complex composition of OMW and its high level of toxicity hinders the success of such a method for OMW biodegradation. Therefore, there is a mandatory requirement for inventing new strategies that could find a real world experience, aimed at both reducing water pollution and its reuse.

Recently, Jaouad *et al.* (2016) showed in their research that for an optimal biodegradation of OMW, a dilution of OMW with water until 2 gCOD/L must be achieved. This means that a high amount of water is needed for the best OMW treatment; however, due to its serious cost implication and its low adaptation to countries facing drought problems, this dilution approach remains inefficient. For a practical application of OMW treatment in CAS or MBR, the idea suggested in this study aimed to dilute OMW with domestic wastewater that feeds WWTP instead of water, which could be more economic and more affordable. It essentially consists of mixing this effluent at a gradual mass ratio with domestic wastewater to ensure the biomass acclimation as performed in the present study. A good OMW treatment will be attained according to the results found in a laboratory CAS pilot treating it. The COD of the treated water (152 mg/L) is slightly higher than the given value by Moroccan Standard for Wastewater Discharge (120 mg/L). However, the MLSS concentration (30 mg/L) complies with MLSS standard limits. The second purpose of the strategy is the treatment of OMW in MBR WWTP. The alimentation of MBR is planned to be the same as the CAS WWTP. According to the results reporting, the biodegradation of OMW in a laboratory MBR plant, the MBR will perform higher than CAS to

Figure 7 | SMP substances concentrations (proteins, polysaccharides and humic-like substances) at stable state in CAS and MBR pilots.

treat OMW and thus, giving a treated water respecting largely the Moroccan standards. The removal of COD (107 mg/L) and MLSS (5 mg/L) are significantly lower than the standard values. Even though the removal efficiency of CAS was slightly lower than the MBR, this last seems to be sufficient for OMW treatment regarding the Moroccan context and the legal environment requirements for wastewater discharge. The use of the MBR instead of CAS could be positive from one side, notably because it is delivering water with a good quality, it is flexible and it requires a small footprint. However, considering the economic-financial side, the MBR is both an expensive and high energy-consuming system. Several studies pointed out the cost as a major drawback for MBRs' widespread implementation. For instance, according to the study performed by Kamble *et al.* (2019) using life cycle cost (LCC) approach, they revealed that the capital cost of MBR (24.8 million/millions of L per day (MLD)) was extremely higher than CAS (6.9 million/MLD). Moreover, this study showed that the MBR is a higher energy-consuming process (1.69 MégaJoules/m³) compared to CAS (0.682 MégaJoules/m³). Using the same evaluation approach (LCC), Bertanza *et al.* (2017) demonstrated that the cost of MBR being 12–18 €/p.e/y greater than that of the CAS and, at the same time, it consumes more energy (73 kWh/p.e/y) than CAS (52 kWh/p.e/y).

In Morocco, the activated sludge wastewater treatment plants are implemented in most large cities and locally adapted for the treatment of domestic wastewater. Furthermore, this study revealed that this technology could be fairly applicable and effective for OMW treatment. Then, why is it necessary to seek for another alternative technology like MBR if just the fees of the MBR set up and operation would increase for approximately the same performance deliverance for both plants? Therefore, for the Moroccan context the suitable choice goes to CAS rather than MBR.

From another side, nowadays there is a need of appropriate technologies for water reuse to fight problems of water scarcity and limited rainfall facing Moroccan regions. Several studies showed that CAS through the secondary treatment could produce a good-quality effluent with the removal of the most unwanted elements but still for CAS a tertiary disinfection step is required to ensure microbial quality and to avoid sanitary risks. Disinfection following MBR treatment may not be needed as the latter can provide, on its own, a better removal of microorganisms. Moreover, as noted in the study by Francy *et al.* (2012), the MBR could be more effective in post-disinfection than UV or

chlorine disinfectants, which are the most used in CAS. In this case, the MBR can be proposed as an alternative in post disinfection after the wastewater secondary treatment and as an alternative to the other disinfectants, which are also too expensive, involving high charges for their application and having numerous side effects for the treatment.

CONCLUSION

In this study, the performance of an external ceramic MBR and CAS plants treating OMW was evaluated. In the first step, an acclimation procedure was used in both reactors to ensure the preadaptation of the microorganisms to OMW biodegradation. For that, a progressive increase of OMW content was applied against an easily biodegradable substrate over time. After the acclimation step, the pilots were fed with OMW at 2 gCOD/L respecting rates of 0.2 kgCOD/kgMLVSS/d of organic loading and 8 g/L of MLVSS for MBR and rates of 0.3 of organic loading and 5 g/L of MLVSS for CAS. Biomass acclimation was then successfully obtained in both pilots. However, the MBR showed a better adaptation to operational condition fluctuations than CAS; that was confirmed by both higher and constant COD removal achievement (95%). At a stable state, MBR performed better than CAS. A higher rate of COD removal was attained (95%) for MBR against 86% for CAS pilot. Moreover, permeate of MBR was free from MLSS whereas CAS treated water contained 30 mg/L of MLSS. In addition to that, the fouling was easily managed in MBR and a quite effective water clarification was noticed for CAS. Consequently, CAS was suitable for OMW treatment and MBR could be suggested as an alternative to CAS when a better effluent quality has to be guaranteed.
