Key points:

- The Variscan crust of Pyrenees documents vertical strain partitioning: lateral flow vs upper-crust thickening in the core of Pangea
- We document horizontal strain partitioning between extensional and compressional domains during plate-scale oroclinal bending

- Large-scale strain patterns of bending hot orogens reflect initial conditions (at the onset of bending) and evolving free-boundaries

Abstract

This study investigates how strain is partitioned within hot orogenic belts in a context of plate-reorganization. We document crustal-scale strike-slip shear zones, plate-scale oroclinal bending, and widespread exhumation of deep crustal domains in the core of nascent Pangea plate during late-Variscan times (ca. 310-290 Ma). The role of strain partitioning in the finite strain patterns is first highlighted at regional-scale by a new detailed structural, kinematic, and petrologic analysis of the Chiroulet and Lesponne gneiss domes in the Pyrenees. Vertical strain partitioning in response to N-S shortening-dominated dextral transpression is secondly documented at the scale of the Variscan domains of the Pyrenees, based on a synthesis of recent geochronological, thermobarometrical, and structural data. We show that the mid-lower crust is affected by eastward lateral flow and the upper crust by penetrative thickening and localized thrusting. Local transverse extension in the mid-lower crust illustrates gravity-driven instability favored by the accumulation of anatectic melts in gneiss domes. Finally, we highlight the respective position of extended and shortened area within the Variscan belt during late-Carboniferous/early-Permian that suggests large-scale lateral strain partitioning and reorganization of the weak continental crust in the core of the Pangea. This distribution appears significantly different from other orogens in a similar context of oroclinal bending, resulting in localization of the shortened zones in the core of the belt. This highlights the influence of the initial and boundary conditions, such as the obliquity of the belt to the applied stress field and the location of free-boundaries, on finite strain patterns.

44 1. Introduction

45 The understanding of how convergence is accommodated by the lithosphere remains an
46 important issue in tectonics, for both recent and old orogenic belts (e.g., Conand et al., 2020;
47 Torvela & Kurhila 2020). Mass transfer within a crust subjected to convergence can be variably
48 accommodated, depending on the rheological behavior of the colliding lithospheres (e.g., Davy,
49 1986, Brun, 2002). Under abnormally hot thermal conditions, the weak orogenic crust is
50 subjected to crustal flow and heterogeneous accommodation of strain, which is strongly
51 partitioned (Davy & Cobbold, 1991; Gapais et al., 2009; Chardon et al., 2009; 2011). Strain can
52 be partitioned vertically, combining lateral horizontal flow (i.e., escape) within the weak lower
53 crust and thrusting along the direction of shortening within the upper crust (Cagnard et al., 2006;
54 Chardon et al., 2009; Bajolet et al., 2015). In such a context, the weak and buoyant lower crust
55 can be exhumed up to shallow levels in response to gravity instability, leading to the formation of
56 syn-convergence gneiss domes (Teyssier & Whitney, 2002; Yin, 2004; Whitney et al., 2004;
57 Cagnard et al., 2007; Chardon et al., 2009). Strain can also be partitioned laterally, leading to the
58 coeval development of thrust, strike-slip, and extensional zones through orogens (Teyssier &
59 Whitney, 2002; Tikoff et al., 2004). Both vertical and horizontal strain partitioning are
60 significantly enhanced in a context of orocline formation (Bajolet et al., 2013; Johnston et al.,
61 2013; Krýza et al., 2019). The Himalayan-Tibet orogenic system, bordered by the Pamir-Punjab
62 and the Namche Barwa syntaxes at its western and eastern edges, respectively, fully illustrates
63 the impact of both lateral and vertical strain partitioning in hot orogens. Indeed, strain is
64 accommodated by thrusting at the front of the belt while the ductile crust from the orogenic
65 plateau is extruded laterally and transversally, exhuming deep crustal rocks within gneiss domes
66 along with the Himalayan ranges (Tapponnier et al., 1982; Gapais et al., 1992; Clark & Royden,

2000; Stephenson et al., 2001; Beaumont et al., 2001; Taylor & Yin, 2009). Lateral-escape accommodation by wrenching is well-expressed at the edges of the belt, and especially in response to the development of orogenic syntaxes (e.g., Searle 1996; Bosboom, et al., 2014; Bajolet et al., 2015). As noticed by several authors, the Himalayan-Tibet system shares similar structural patterns with the Variscan belt of Western Europe (e.g., Matte 1991, Vanderhaeghe & Teyssier, 2001). Indeed, the Variscan belt was characterized by coeval development of crustal-scale, strike-slip shear zones (Fig. 1, e.g., Arthaud & Matte, 1975; Matte, 2001; Carreras & Druguet, 2014; Díez Fernández & Pereira, 2017), plate-scale oroclinal bending (Fig. 1, e.g., Gutiérrez-Alonso et al., 2004; Weil et al., 2010) and widespread exhumation of deep crustal domains (e.g., Burg et al., 1994; Martínez Catalán et al., 2007; Gapais et al., 2015; Authemayou et al., 2019). While most of the tectonic models focused on strain partitioning within the collapsing hinterland, only a little attention was paid to strain patterns from the foreland of the belt and the link between them was poorly investigated. But both the hinterland and the southern foreland of the Variscan belt were affected by a diffuse and late reorganization of early orogenic structures during the late-Carboniferous to the early-Permian period (310-290 Ma). It is associated with high-to ultra-high temperature metamorphism (Pin and Vielzeuf, 1983; Barbey et al., 2015; Kunz et al., 2018), and bi-modal magmatism that has affected the whole southern part of the Variscan belt (Martínez Catalán et al., 2014; Moyen et al., 2017; Petri et al., 2017; Lemirre et al., 2019). The widespread high-temperature event suggests lithospheric-scale thermal anomaly associated with the removal of the lithospheric root (Gutiérrez-Alonso et al., 2004; Buzzi & Gaggero, 2008; Laurent et al., 2017). The southern foreland of the Variscan belt centered on the Cantabrian orocline and the Variscan domain from the Pyrenees were also affected by this thermal anomaly despite these domains did not suffer significant thickening before the high-

temperature deformation event (de Saint Blanquat et al., 1990; Weil et al., 2013; Cochelin et al., 2017).

In this context, the common history of the Cantabrian orocline and the Variscan domains of the Pyrenees during late-Variscan evolution remains a significant issue to understand late mountain range evolution and crust-mantle interactions. The Cantabrian orocline located at the core of the Iberian Armorican arc (Fig. 1), is associated with about 180° of cumulative vertical rotation (clockwise and counter-clockwise for the northern and the southern limbs, respectively) of early orogenic structures (Weil et al., 2013; and references therein) between 305 and 295 Ma (Weil, 2006; Weil et al., 2010). Two typical strain patterns were recognized around this late-orogenic structure, depending on their position within or at the limbs of the arc. The core of the arc (i.e., the Cantabrian Zone) is characterized by contractional structures, such as arc-radial folds and steep E-W striking thrusts (e.g., Pérez-Estaún et al., 1988; Bahamonde et al., 2007; Merino-Tomé et al., 2009; Pastor-Galán et al., 2014; Blanco-Ferrera et al., 2017; García-López et al., 2018, Fig. 1). To the contrary, the branches of the arc (e.g., Armorican massif, Central Iberian Zone) exhibit arc-parallel stretching, accommodated by both lateral wrenching and extension (e.g., Martínez Catalán et al., 2007; Gapais et al., 2015; Díez Fernández & Pereira, 2017; Authemayou et al., 2019). Based on this apparent opposition, it has been proposed that the cause of oroclinal bending is an active buckling at lithospheric-scale that was responsible for contrasted mass transfers in the arc, depending on the relative position in the inner and outer arc (Gutiérrez-Alonso et al., 2012). However, compressive/transpressive tectonics is not restricted to the core of the Cantabrian orocline but seems to have developed coevally in the rest of the southern Variscan belt (i.e., the Gondwanan margin), such as the Alpine External Crystalline Massifs (Fréville et al., 2018), the Maures-Tanneron and Corsica-Sardinia massifs (Rolland et al., 2009; Casini et al., 2015), the

113 Meseta (Alleghenian belt, Michard et al., 2010; Delchini et al., 2018) and the Axial Zone of the
114 Pyrenees (Cochelin et al., 2017) (Fig. 1).

115 The Variscan domains of the Pyrenees provide excellent markers to study the influence of
116 combined lateral and vertical strain partitioning during structural plate reorganization that led to
117 oroclinal bending. These domains consist of a late-Variscan (i.e., 310-290 Ma) transpressive
118 segment that corresponds to the so-called Pyrenean Axial Zone and sparse massifs under
119 Mesozoic cover to the North, the North Pyrenean massifs (NPM) (Fig. 2a). The lower crust was
120 affected by lateral horizontal flow while the upper crust was strongly squeezed and affected by
121 thrusting along the direction of shortening (Cochelin et al., 2017; 2018a). This structural pattern
122 highlights a very peculiar crustal-scale type of deformation in the foreland of the Variscan belt
123 during its late structural reorganization.

124 This paper aims to clarify the role of multi-scale strain partitioning in the tectonic evolution of
125 orogenic belts subjected to a structural late-reorganization and bending by focusing on the
126 southern part of the Variscan belt, which is located in the core of Pangea during the late-
127 Carboniferous to early-Permian period. To address this issue, we illustrate how vertical strain
128 partitioning controlled gneiss dome formation in the Pyrenees by providing a new structural,
129 kinematics, and petrological study on the Chiroulet and Lesponne massifs, located at the north-
130 western corner of the Axial Zone (Fig. 2a). Coupled with a synthesis of published structural,
131 geochronological, and metamorphic data from the whole Variscan domains of the Pyrenees (Figs.
132 2b & 2c), these data are integrated at the scale of the southwestern Variscan belt. We highlight
133 how the interaction between localization of mantle heat source and large-scale vertical and lateral
134 strain partitioning led to the coexistence of strike-slip, compressional/transpressional, and
135 extensional/transtensional tectonic belts. By comparing the Variscan belt of Western Europe with

the west Himalayan syntax, we discuss the influence of initial and boundary conditions and thermal states of the colliding lithospheres on finite strain patterns in a context of lithosphere bending.

2. Geological setting

2.1 The Variscan domains of the Pyrenees in the Variscan belt

The Western Europe massifs (i.e., Armorican Massif, Iberian Massif, French Massif Central, Bohemian massif, Fig 1) recorded a late-Carboniferous to early-Permian orogenic dismantling associated with high-thermal conditions. This plate-scale event took place after a period of amalgamation of a series of micro-plates with Laurussian margin and a major collisional event of these amalgamated continental blocks with the Gondwana land-mass, during Devonian and Carboniferous times (e.g., von Raumer et al., 2013; Edel et al., 2018; Lotout et al., 2020).

During the main collision phase in Western Europe massifs, the Variscan domains of the Pyrenees corresponded to the distant foreland of this orogenic system that recorded deep-sea to platform sedimentation at Devonian to mid-Carboniferous times (see García-Sansegundo et al., 2011 and references therein) and ultimately turbiditic deposition (Delvolvé & Perret, 1989). Flysch deposition is associated with an early tectonic phase, called D1, that was locally preserved as a relic in the Axial Zone (Cochelin et al., 2017 and references therein). Where preserved, D1 features are characterized in the upper crust by south-westward to westward thrusts and recumbent or overturned folds (Matte, 2002; Cochelin et al., 2017). These structures induce no significant stratigraphic or structural breaks and were interpreted as reflecting thin-skinned tectonics in the distant foreland of the Variscan belt, between 325-310 Ma (Cochelin et al., 2017). Few occurrences of foliation relics were noticed in the mid-to-lower crust but its relation with D1

structures observed in upper crustal levels remains unconstrained (de Hoÿm de Marien et al., 2019). The D1 tectono-metamorphic event in the Pyrenees is poorly recorded, but it is supposed to produce moderate thickening of the crust, as exemplified by preserved occurrences of prograde M1 metamorphism (Barrovian) in the Canigou massif (de Hoÿm de Marien et al., 2019, Fig. 2c). A slight increase of pressure of about 1 kbar, from 5.5 to 6.5 kbar, has been reported by these authors.

Late Variscan deformation under a high-temperature regime is responsible for the strain pattern of the Variscan domains of the Pyrenees. This strain pattern is marked in the Axial Zone by two distinct structural levels, the so-called Superstructure and Infrastructure (De Sitter & Zwart, 1960) that corresponds to the upper and mid-lower crustal levels, respectively. The Superstructure is made of low-grade Paleozoic metasedimentary rocks affected by intense folding (Carreras & Capella, 1994), an associated N100°E-striking steep axial plane cleavage (Fig. 3) bearing vertical stretching lineations and host the large calc-alkaline plutons (Cochelin et al., 2017; 2018a,b). The Infrastructure corresponds to the partially molten mid-lower crust that is observed within longitudinally elongated gneiss domes (Denèle et al., 2007; 2009; Mezger, 2009). These gneiss domes are defined by shallowly dipping foliation planes bearing longitudinal (i.e., parallel to the belt) stretching lineations (Fig. 3; Cochelin et al., 2018a). In details, the Superstructure is characterized by an incomplete fan of schistosity, interrupted by Alpine faults, especially the North Pyrenean Fault (NPF) to the North, with a vertical domain in the northern half part of the Axial Zone and a domain of dip decreasing southward (Zwart, 1979; Cochelin et al., 2018a). Geostatistical analysis of cleavage suggests that the zone affected this fan of schistosity was initially 80-100 km wide (Cochelin et al., 2018a). Furthermore, the northern domain localized near the NPF was mainly affected by apparently intense coaxial (i.e., non-

181 rotational) deformation while the southern one is characterized by non-coaxial “north side up”
182 (i.e., the northern block goes upward and the southern downward) or “top to the south” shearing.
183 A dextral component of shearing is also observed and appears restricted to the vicinity of plutons
184 and gneiss domes (Cochelin et al., 2018a). Within gneiss domes belonging to the Infrastructure,
185 the direction of stretching tends to evolve vertically from E-W in the core of gneiss domes to
186 oblique or transverse at their roof (Fig. 3). There, strain localization can be observed within the
187 andalusite zone forming retrogressive extensional shear zones (Van den Eeckhout & Zwart, 1988;
188 Mezger & Passchier, 2003; Cochelin et al., 2017; Le Bayon & Cochelin, 2020). The gneiss
189 domes are mostly folded, with folds showing steep or south verging overturned limbs that are
190 partially reworked by steep reverse-dextral shear zones (Carreras et al., 1980; Vilà et al., 2007;
191 Denèle et al., 2007; 2008; 2009). These reverse-dextral shear zones have been developed under
192 amphibolite-to-greenschists facies conditions and defined an anastomosed network that has
193 affected the evolution of gneiss domes (Denèle et al., 2007; Cochelin et al., 2018a) and the
194 dynamics of pluton emplacement (Gleizes et al., 1998; Denèle et al., 2008).

195 The mode of formation of the Superstructure and the Infrastructure was widely debated since the
196 '60s (e.g., see Carreras & Capella, 1994) but a coeval formation under N-S shortening-dominated
197 transpression, called D2, reached consensus since two decades (e.g., Gleizes et al., 1998; Mezger,
198 2009; Denèle et al., 2014; Cochelin et al., 2017). Coeval formation of these two structural
199 domains was interpreted as reflecting vertical strain partitioning between a partially molten and
200 hot middle crust and the cold upper crust (Denèle et al., 2007; 2009; Cochelin et al., 2017). It
201 should be noted that this vertical structural zonation was only partially recognized in the NPM.
202 While a transpressional regime was advocated in the Trois-Seigneurs and the Agly massifs
203 (Leblanc et al., 1996; Gleizes et al., 1998; Olivier et al., 2004), the other massifs (Ursuya,

204 Castillon, St Barthélémy) have been affected by crustal thinning, permitting the exhumation of
205 Low-Pressure granulites thanks to the activation of extensional shear zones/detachments bearing
206 mainly transverse direction of stretching (Fig. 3) (de Saint Blanquat et al., 1990; Cochelin et al.,
207 2017, Saspiturry et al., 2019). In the Agly massif, crustal thinning was described as occurring
208 during dextral transpression (Olivier et al., 2004; Vanandois et al., 2020; Siron et al., 2020).

209 The late-Carboniferous/early-Permian thermal anomaly is characterized in the Variscan massifs
210 of the Pyrenees by partial melting of the mid-lower crust under Low-Pressure amphibolite facies
211 in the Axial Zone and Low-Pressure granulite facies in the NPM (Vielzeuf, 1984; de Saint
212 Blanquat et al., 1990; Guitard et al., 1996; Vilà et al., 2007; Aguilar et al., 2015, Lemirre, 2018,
213 Figs. 2c, d & e). In details, available PT estimates for peak metamorphism show that apparent
214 metamorphic gradient within the crust of the Pyrenees at ca. 300 Ma can be divided into two
215 parts (Figs. 2d & e), i) a first part showing high metamorphic gradients (i.e., between 55 and
216 90°C/km) up to ca. 3 kbar and ii) nearly isothermal conditions within the partial molten middle
217 crust. Temperature peak in the middle crust is around 700-750°C within the Axial Zone and 800-
218 850°C within the North Pyrenean Massifs, corresponding to the wet solidus and biotite
219 dehydration melting reaction respectively (Figs. 2d & e). In most of the gneiss domes,
220 exhumation favored by extensional shearing is well imaged by clockwise PT paths (Fig. 2c),
221 implying nearly isothermal decompression (e.g., Roc de France), heating and decompression
222 (e.g., the Bossost dome), or cooling and decompression (the Albères massif, Fig. 2c). Locally,
223 decompression was followed by heating and a slight increase in pressure (e.g., the Canigou and
224 Aston domes, Fig. 2c).

225 Partial melting in the mid-lower crust is associated with intrusion of numerous large calc-alkaline
226 plutons in the upper crust (i.e., between 2 and 3 kbar, Fig. 2c) and leucogranites or mafic sills in

the middle crust (i.e., for pressure higher than 3 kbar; Debon et al., 1996; Denèle et al., 2014; Kilzi et al., 2016). These calc-alkaline plutons are made of successive intrusion of magmas from gabbroic to granitic compositions having hybrid to mantle sources (Debon et al., 1996; Lemirre et al., 2019). Magmatism mainly took place between 305 and 290 Ma, coevally with the D2 transpressional phase (Denèle et al., 2014; Druguet et al., 2014; Kilzi et al., 2016; Lopez-Sanchez et al., 2018; Lemirre, 2018; Lemirre et al., 2019, Fig. 2b). Magmatism may have started earlier locally (Aguilar et al., 2014; Lopez-Sanchez et al., 2018; Schnapperelle et al., 2020) and continued up to 270 Ma in the Basque and North Pyrenean Massifs (Fig. 2b).

2.2 The Chiroulet and Lesponne domes in the northwestern corner of the Pyrenean Axial Zone

The Chiroulet and the Lesponne massifs correspond to two neighboring gneiss domes, located in the north-western corner of the Axial Zone between the Néouvielle pluton to the south and the NPF to the north (Fig. 3). Forming two 15 km long and 5 km wide elliptical bodies, they represent the smallest gneiss domes of the Axial Zone. The Lesponne dome sensu-lato corresponds to a succession of three sub-domes, the Lesponne sub-dome sensu-stricto, the Aigue-Rouye sub-dome, and the Gripp anticline from west to east, respectively (Fig. 4a). Along with the Bossost dome located in the Central Axial Zone (Fig. 3), the Chiroulet-Lesponne domes are the shallowest of the Axial Zone, as sillimanite and andalusite isograds reached the upper Paleozoic series (Pouget, 1984; Ternet et al., 1996). The case of the Chiroulet massif is unique in the Axial Zone because the anatexis front is located at the transition between Silurian black schists and Devonian limestones while it is located in lower Paleozoic rocks in the other massifs (Guitard et al., 1996 and reference therein). The core of these gneiss domes is composed of metatexites and bimodal plutons (diorites and leucogranites) for the Lesponne dome, and diatexites with

leucogranite sheets for the Chiroulet dome. Metamorphic conditions of partial melting have been estimated at ca. 700 °C and 4.2 kbar in the Lesponne dome (i.e., at mid-crustal depths, see Lemirre et al., 2019, Fig. 2b). Geochemistry shows that the dioritic magma is associated with a mantle source while leucogranites are issue from partial melting of surrounding metasedimentary rocks (Lemirre et al., 2019). In the Lesponne and Chiroulet massifs, partial melting started at ca. 303 Ma and the final crystallization of magmas occurred at ca. 290 Ma, suggesting that the mid-lower crust stayed hot (i.e. around 700°C) and partially molten during 10 My (Lemirre et al., 2019, Fig. 2c). Based on petrostructural studies, Pouget (1984, 1987) and Pouget et al., (1989) have proposed that these massifs form two magmatic diapirs intruding the upper crust in a context of orogenic collision. However, the absence of published mineral-stretching lineation measurements or kinematic data makes it difficult to ascertain the tectonic context of their formation.

3. Methods

This work is based on 197 field stations, where petrographic, structural and kinematic analysis were performed (see Supporting Information). To retrieve how the gneiss domes were emplaced within the upper crust, planar and linear strain fabrics and kinematic criteria were systematically measured. The studied area is characterized by the interference between two regional penetrative fabrics. The first defines the main foliation within migmatites, paragneiss, and sillimanite-andalusite bearing micaschists. The second is an axial plane cleavage, moderately to steeply dipping to the south, mainly observed in upper crustal low-grade rocks. This cleavage is marked by oriented biotites and chlorites. As these two fabrics characterize respectively the Infrastructure (i.e., the middle crust) and the Superstructure (i.e., the upper crust), we call them “Si” and “Ss” respectively, following Cochelin et al., (2017) and consequently, the same terminology will be

used for lineations (Li and Ls). Specific attention was paid to the transition between Si and Ss fabrics and we present hereafter their structural relationship by showing the observed interference patterns. These results allow us to propose a revised and harmonized geological map of the area (see Supporting Information), and a structural map based on the compilation of available data and our measurements (Fig. 4b). Our dataset is also presented in Figure 5. New cross-sections over the two massifs (Fig. 6) and field observations (Figs. 7, 8 & 9) are presented, highlighting structural patterns within the upper and middle crust. Besides, 34 samples were collected within the two gneiss domes and their surrounding metasedimentary rocks. Thin-sections were prepared normal to the schistosity and parallel to the mineral-stretching lineation (XZ planes) for petrographic and microstructural analysis (Fig. 10).

4. Results

From a structural point of view, the studied area is divided into three domains: i) the core of the gneiss domes made of migmatites, plutonic rocks (e.g., leucogranite, diorite), and paragneisses, where only Si is observed; ii) the upper crustal domain, where Ss is the main fabrics; and iii) a transitional zone in-between, that has affected the Devonian rocks belonging to the sillimanite-andalusite zone, where interference patterns between Si and Ss can be found. We present hereafter these three domains from bottom to top.

4.1. The lower domain

The lower domain can be defined under the sillimanite-in isograd where gneissic rocks (metatexites and paragneiss) and micaschists show evidence of plastic deformation of quartz, feldspar, phyllosilicates, and alumina silicates that define the foliation Si and the stretching lineation Li.

295 The map of foliation trajectories highlights a first-order concentric pattern centered on high-grade
296 rocks that define two gneiss domes with N110° and N130° long axis, for the Lesponne and
297 Chiroulet massif, respectively (Fig. 4). Foliation trajectories in north-south cross-sections (Fig. 6)
298 show that the Lesponne dome is upright and symmetrical while the Chiroulet dome is
299 asymmetrical and inclined, with foliation dominantly dipping to the south. The northern limb of
300 the Chiroulet dome is characterized by S-steeply dipping foliation suggesting a domal shape
301 overturned to the north (Figs 4b & 6). The internal structure of the domes displays second-order
302 sub domes (Fig. 4b) with apexes that correspond to the core of magmatic bodies or diatexites in
303 the Lesponne and Chiroulet domes, respectively (Fig. 4). Magmatic rocks (leucogranites and
304 diorites) and diatexites are characterized by more or less defined magmatic foliation and lineation
305 (Fig. 7a, b & c). Structural concordance between the intrusive contact of diorite-leucogranite
306 plutons with their country-rocks and the foliation Si suggests intrusion as magmatic sills (Figs. 6
307 & 7a). Moreover, consistency between magmatic mineral lineations within magmatic bodies and
308 stretching lineations within their country-rocks reflects that they were deformed synchronously
309 during magmatic events. Mineral/stretching lineations are defined by elongated quartz
310 aggregates, oriented feldspars, patches of micas (Fig. 7c), or oriented amphiboles (Fig. 7d) and
311 show a consistent N110° trend in the Chiroulet dome and N130° in the Lesponne dome (Fig. 4b).
312 Stretching is associated with strain localization into shallowly dipping C' shear bands with a
313 consistent “top to the west” sense of shear (see Cochelin et al., 2017, Fig. 10c). Injection of
314 magmatic veins is common in these shear bands, suggesting deformation during partial melting.
315 At the boundary between the lower domain and the transitional domain of the Chiroulet dome,
316 stretching lineations turn to N-S (Fig. 4b) and C/S structures (following the definition by Gapais,
317 1989) can be observed within leucogranitic sills, with “top to the south” kinematics (Fig 6, see

318 Lemirre et al., 2019). Calc-silicate gneisses at the top of the migmatites are affected by antithetic
319 slip boudinage (i.e., domino-like) compatible with “top to the south” shearing (Fig. 7e).

320 The microstructural study shows that paragneisses and sillimanite-bearing micaschists of the
321 lower domain from the two domes are characterized by strongly oriented fabrics (Figs. 10b, c &
322 d). The association of deformation bands in quartz grains as well as evidence of dynamic
323 recrystallization controlled by grain boundary migration (Fig. 10b) attest to deformation at high-
324 temperature conditions, i.e. $>500^{\circ}\text{C}$ (Stipp et al., 2002; Fossen and Cavalcante, 2017). In the
325 calc-silicate gneisses at the top of the migmatites, S_1 foliation is parallel to the transposed
326 bedding defined by the alternation of diopside-epidote-sphene layers and garnet-diopside-sphene
327 layers (Fig. 10d). Garnet-rich layer form boudins and the inter-boudins are mostly filled by quartz
328 or calcite-epidote veins (Fig. 10d). In these veins, quartz grains are also recrystallized by grain
329 boundary migration (Fig. 10d’).

330 4.2. The transitional domain

331 This domain affects the upper Paleozoic series. It is distributed in a large region in the Chiroulet
332 dome that corresponds globally to the extension of the andalusite-bearing micaschists and is
333 localized within the Silurian black schists in the Lesponne dome. In the Chiroulet dome, the basal
334 limit of the transitional domain corresponds to the contact between the Silurian black schists
335 turned into paragneisses and the Lower Devonian meta-carbonates, both within the sillimanite
336 zone. The upper part of this domain can reach the Upper Devonian series and the Tourmalet shear
337 zone in the southern part of the massif (Figs 4 & 6).

338 In the transitional domain, a high-strain fabric is marked by the total transposition of the bedding
339 and the development of a pervasive S_1 foliation. It is responsible for the boudinage of Devonian

340 siliciclastic layers within the weak marbles. Li stretching lineation is defined by calcite,
341 pyroxene, or amphibole in marbles and sillimanite, andalusite, feldspar, or quartz in schists and
342 paragneisses.

343 Foliation trajectories show concentric patterns, surrounding domes' cores (Fig. 4b). These
344 foliation trajectories appear highly disturbed by polyharmonic N100° to N130° trending folds,
345 and specifically in the southern border of the Chiroulet dome (Fig. 4b). First-order folds are
346 kilometer-scale, tight to isoclinal (Fig. 6). They exhibit asymmetrical shapes and are all
347 overturned to the north (Figs 6 & 8a). Similar folds may be recognized from meter to decameter
348 scale (Fig. 8). These numerous folds are responsible for multiple repetitions of the schists-
349 marbles intercalations, which could explain why the sillimanite-andalusite metamorphic zones
350 are thicker where these folds exist (Fig. 6).

351 Li show extremely variable trends, from roughly N-S to E-W but remain dominantly parallel to
352 the Li of the lower domain (Fig 5). On the field, the stretching lineation appears wrapped into
353 regional to local folds (Fig. 7f), suggesting passive reorientation by folding of the Si fabric. When
354 C' shears are associated with stretching, the relative sense of shear is also variable depending on
355 their location in regional folds (Figs. 4b, 5 & 6).

356 The intense folding of the Si foliation is associated with the development of an N100-130°E axial
357 plane cleavage (Figs 4b & 6). Within the hinges of folds, it forms a crenulation cleavage Ss (Fig.
358 7g), which is marked by the crystallization of biotites in andalusite-sillimanite schists. Ss is E-W
359 striking and dips moderately to the south (Fig. 5). Localization of deformation in the flanks of
360 regional folds is recorded by the development of a mylonitic foliation mostly developed within
361 the marbles (Fig. 9a). Strain localization strongly reduced the thickness of marbles while tectonic
362 thickening is currently seen at the hinges (Figs 6 & 8a). Folded boudins are common (Fig. 8b, c,

d), which suggests reworking of Si fabric. This mylonitic foliation Ss in marbles bears an N200° down-dip stretching or striae-lineation Ls (Fig. 5), defined by calcite or quartz ribbons (Fig. 7h). Ls lineations are systematically associated with non-coaxial “top to the north” (i.e., reverse) or “South side up” kinematics (Figs 6, 8a,e, & 9a). North-directed thrusting is in accordance with the regional asymmetry of the sheared folds. Similar deformation can be observed within Silurian black schists at the top of the Lesponne gneiss dome, with strain localization of non-coaxial “top to the north” (i.e., reverse) shearing associated with N-S stretching lineations (Fig. 9b). This mylonitic contact has been locally reworked by post-Variscan faulting (see *section 4.4.2* below). At the top of the transitional zone, the Si fabric appears mostly reworked by the steep and penetrative Ss cleavage, with locally few preserved andalusite porphyroclasts. Stretching lineations are still down-dip and kinematics associated with shear bands seems to be mostly reverse (Figs. 4b & 6).

The microstructural study within the limbs of the tight to isoclinal regional folds shows the reworking of the high-temperature Si foliation by Ss mylonitic bands (Fig. 10e, e'). Core and mantle textures characterized the Ss planes (Fig. 10e) with quartz 1 ribbons and a fine-grained matrix of quartz 2 and muscovite forming the core and the mantle, respectively. Undulose extinction and deformation bands in quartz ribbons, as well as the presence of fine quartz grains, underline deformation at middle-temperature conditions probably around 400-450°C, close to the bulging/subgrain rotation transition defined by Stipp et al. (2002).

Near the boundary with the upper domain, chistalitic-andalusites are partially retrogressed into white micas while biotites are retrogressed into chlorites (Fig. 10f). Chlorite is also formed in pressure shadows of andalusite porphyroclasts (Fig. 10f, f'). Andalusites show inclusions of an early fabric that could be related to peak metamorphism (i.e., Si foliation) (Fig. 10f'). Quartz

grains document evidence of subgrain rotation recrystallization, with quartz blasts of about 20-50 μm (Fig. 10f'), suggesting that deformation occurred at a temperature around 400-500°C (Stipp et al., 2002). The retrogression of biotite, andalusite, and subgrain rotation recrystallization of quartz suggest that reworking of Si by Ss is associated with regional cooling from amphibolite to greenschist facies conditions. These observations are in accordance with estimates at 580°C/2.3 kbar by Pouget (1989) for the peak of metamorphism associated with Si in the transitional domain.

4.3. The upper domain

This upper domain belongs to the biotite and chlorite zones, where the original bedding of the upper Paleozoic series is mainly preserved. These metasedimentary rocks are affected by tight E-W to NW-SE trending folds and a steep axial plane cleavage (Fig. 6). Ss trajectories are molding the gneiss domes, forming neutral points that are preserved at their western parts (Fig. 4b). Locally, strain seems to be localized within Devonian marbles or Silurian black shales, where bedding is transposed. These high-strain zones delineate the longitudinal regional shear zones observed outside of the metamorphic aureoles of gneiss domes (Figs. 3 & 4, e.g., the lateral continuity of the Tourmalet shear zone). The stretching lineations Ls lying on the Ss fabrics have an N200° trend, which is parallel to the Ls measurement within the transitional domain (Fig. 5). Ls is mostly defined by quartz aggregates, calcite ribbons, or white micas flakes. Sense of shear associated with shear planes depends on the dip direction of the shear planes and Ss, showing systematically reverse kinematics (Figs. 5 & 9b). The transition between the two directions of thrusting seems to coincide with the Tourmalet shear zone, with the first occurrences of south-verging thrusts and north-dipping Ss cleavage that are well known in the rest of the Axial Zone (Figs 4b & 6, cross-section 1).

The microstructural study of the Upper Carboniferous sandstones (Fig. 10a) evidences a well-defined cleavage Ss, marked by dissolution joints (Fig. 10g). The matrix is made of very fine grains of quartz, muscovite, and chlorite. Detrital quartz grains are poorly or not recrystallized, showing undulose extinction while quartz from the matrix form aggregates of small crystals showing homogeneous grain size probably developed by bulging recrystallization (Fig. 10g'). It suggests that deformation occurred at temperatures below 400°C (Stipp et al., 2002), in agreement with estimates from Pouget (1989) (400-220°C/2.3 kbar) for the peak metamorphism. The detrital quartz grains show symmetrical patterns, which indicates that deformation was mainly coaxial.

4.4 Early and late deformations:

4.4.1. Early (D1) deformation

In the studied area, occurrences of early deformation can be deduced at a map-scale in the upper domain (Fig. 4). Indeed, moderate overprint of Ss on bedding allows preserving early D1 folds, highlighted by intercalated limestones within Devonian schists (Fig. 4). These pre-Ss folds were variably rotated, showing N-S to ENE-WSW trends outside and near gneiss dome, respectively. Regarding the E-W cross-section (Fig. 6, cross-section 3), it appears that the dome shape of the Lesponne is oblique to regional structures as the gneiss dome was emplaced into Cambro-Ordovician rocks at the east and lower Devonian series at its western termination. This suggests regional west-verging overturned or recumbent folds, like those observed in the western part of the Axial Zone (Matte, 2002; Cochelin et al., 2017). In our studied area, the characteristics of the D1 deformation event are difficult to determine at the scale of the outcrops and no proofs of the existence of an early cleavage S1 have been underlined in the field.

4.4.2. Late and post-Variscan deformation

The magmatic rocks belonging to the lower domain were affected by localized low-grade (i.e. chlorite stability field) ductile deformation (Fig. 4). It forms E-W to NW-SE meter-scale mylonitic corridors that have been precisely mapped by Pouget (1984), showing an anastomosed pattern. These corridors are steeply dipping and induce local perturbations of S_1 trajectories (Fig. 4b). As described by Pouget (1984), mylonites are marked by small porphyroclasts of quartz and feldspars and by crystallization of white mica, chlorite, or epidote. The foliation mostly hosts a shallow-dipping stretching lineation, defined by quartz aggregates. Steep C' shears show dextral kinematics (Fig. 9c), which is consistent with the local inflection of S_1 trajectories (Fig. 4b). A minor vertical component of movement is inferred because of shallowly plunging (i.e. with a pitch between 5 to 45°) stretching lineations. The main low-grade dextral shear zone corresponds to the Chiroulet shear zone, putting diatexites of the northern part of the Chiroulet massif in contact with lower Devonian rocks or small sheets of Silurian black schists belonging to the andalusite zone (Fig. 6). Following Pouget, (1984), these ductile shear zones could also affect the upper domain laterally and are collinear to the regional S_s fabric. Therefore, these shear zones could be Late Variscan in age, like those described in *section 4.3*.

In our studied area, late brittle deformation can be frequently observed and may be related to the Alpine orogeny. The frequency of faults increases towards the north (i.e., towards the NPF, see Fig. 4). They often reactivate Variscan structures such as S_s cleavage or S_1 foliation plane, with down-dip striation covering the foliations planes with HT paragenesis (e.g., sillimanite, andalusite, biotite, see Fig. 9d & d'). When structural markers are present, such as post-Variscan dykes (Fig. 9d), the faults show reverse sense of shear. Most of the time, Silurian black schists localized faulting, especially around the Lesponne massif. Unfortunately, the amount of

displacement along these faults during Alpine orogeny remains difficult to estimate, as the current position of rocks results from both Variscan and Alpine tectonics. Furthermore, few contacts such as the Oussouet-Cap de la Taoula thrust, seem to have experienced a more complex history, including Post-Variscan normal faulting that could be Permian or Cretaceous in age. Indeed, the reverse movement along the thrust was not sufficient to balance earlier normal faulting (Fig. 6, compare cross-sections 4 & 5). Despite reactivation of Variscan structures, the impact of Alpine faulting remains limited as it doesn't disturb the metamorphic aureoles of gneiss domes (e.g., the andalusite zone of the Lesponne dome stays centered on the sillimanite zone, Fig. 4). Tilting to the north of Variscan structures can be observed at the vicinity of the NPF like in the rest of the Axial Zone (see Cochelin et al., 2017) but this effect vanished 1-2 km south of the fault (Ternet et al., 1996). The structural and metamorphic continuity and the absence of large block rotation are thus well presented in our cross-sections (Fig. 6).

5. Discussion

5.1. Gneiss dome formation by vertical strain partitioning

Based on our structural and microstructural observations, and the integration of petrological and geochronological data, we propose a scenario in which the Chiroulet-Lesponne gneiss domes were formed in two steps during the D2 tectonic phase (Fig. 11). The two steps, that follow up an early folding event in the upper crust (D1 phase Fig. 11a), have occurred in a continuum during progressive cooling of the crust, subsequent to peak metamorphism and partial melting.

5.1.1. Initiation of gneiss dome formation during longitudinal mid-crustal flow

Deformation at peak metamorphic conditions is marked by strain partitioning between the upper crust and the partially molten middle crust. The metasedimentary rocks of the upper crust were

476 subjected to vertical stretching, folding, and formation of a steep axial plane cleavage. Syn-
477 kinematic plutons such as the Néouvielle pluton to the South of the Chiroulet dome were
478 emplaced in the upper crust and were affected by a weak deformation at sub-solidus to HT solid-
479 state conditions (Gleizes et al., 2001). This deformation, already described in the Axial Zone to
480 the East of the Chiroulet-Lesponne area, is compatible with N-S shortening-dominated
481 transpression and probably occurred from 310 to 300 Ma, during the main phase of pluton
482 emplacement.

483 The mid-lower crust recorded orogen-parallel flow (i.e. longitudinal) and formation of gneiss
484 domes (Fig. 11b). Gneiss dome formation suggests both gravitational instabilities linked to the
485 presence of partially molten rocks and strain localization that induced local upward flow.
486 Exhumation of gneiss core is marked by an isothermal decompression path in the migmatites, up
487 to ca. 3 kbar while the transitional domain recorded only a minor decrease of temperature (Fig.
488 11b). The impact of strain localization is identified by the contrasted evolution of the Chiroulet
489 and Lesponne domes. The Lesponne dome is in fact, only affected by lateral flow while the
490 Chiroulet dome is marked by the development of a transverse extensional shear zone on the
491 whole pile of Devonian metasedimentary rocks (Fig. 11b). This contrasted style of evolution is
492 correlated with various metamorphic conditions in the Devonian series of the two domes. This
493 suggests an upward propagation of the thermal anomaly in an already structured crust, inherited
494 from the D1 phase (Fig. 11a). The local weakening of Devonian marbles explains the formation
495 of a kilometer-scale decollement level above the migmatites of the nascent Chiroulet dome (Fig.
496 11a, b). Similarly, local orogen-normal extension assisted by strain localization within marbles
497 was also recognized in the Bossost dome located few kilometers to the east (Mezger & Passchier
498 2003; Cochelin et al., 2017) or in the Canigou dome (Le Bayon & Cochelin, 2020).

499 This event recorded in the Chiroulet-Lesponne area expresses a turning-point of tectonic settings
500 and style of deformation. This turning-point has already been described in the Central and
501 Eastern domains of the Axial Zone synchronously with the widespread metamorphism and
502 magmatism taking place at ca. 310-290 Ma (e.g., Denèle et al., 2014; Lemirre et al., 2019, Fig.
503 2b). The upward migration of the anatexis front progressively increased the geothermal gradient
504 in the above crust and led to a near isothermal gradient below (Lemirre, 2018; Lemirre et al.,
505 2019). The persistence of this HT geothermal gradient during at least 10 Ma (Lemirre et al.,
506 2019, Fig. 2b) produced a long-lasting weakening of the crust.

507 5.1.2. Dome amplification and strain localization

508 Cross-cutting relationships of Ss and Si in the transitional domain, the late formation of north-
509 verging folds and thrusts surrounding the Chiroulet dome, and the formation of chlorite-bearing
510 shear zones that crosscut both the lower and upper crustal domains suggest a continuum of D2
511 deformation during progressive cooling of the crust, after the peak of the thermal anomaly (Fig.
512 11c). Progressive cooling of the crust is attested in a significant way by the reworking of the HT
513 Si fabrics by the MT Ss fabrics in the transitional zone. Crystallization of migmatites at ca. 290
514 Ma (Lemirre et al., 2019) at the top of the gneiss domes seems to constrain the ultimate age of
515 this event. We propose that this period is characterized by a progressive coupling between the
516 transitional domain at the top of the mid-lower crust and the upper crust implying competition
517 between orogen-parallel horizontal flow within the mid-lower crust and vertical stretching in the
518 upper crust. In this context of cooling, the still weak marbles and micaschists surrounding the
519 Chiroulet dome localized compressional deformation, forming north-verging folds and thrusts
520 (Figs. 6 & 11c), and the domal shapes were amplified by large scale folding (Fig. 11c). In the
521 Lesponne dome, the Silurian black schists localized the deformation, preserving the dome from

intense overprint by Ss structures (Fig. 11c). Progressive strain localization within steep retrogressive shear zones at the limbs of gneiss domes allowed overturning the northern flank of the Chiroulet dome (Fig. 11c). These late-Variscan shear zones are well-known in the Axial Zone (e.g., Carreras, 2001, Druguet, 2001; Denèle et al., 2008; Cochelin et al., 2018b) and their activation was recently constrained using U/Pb dating on apatites at ca. 289 Ma in the Central Pyrenees (Poitrenaud, 2018; Poitrenaud et al., 2020).

5.2. Impact of strain partitioning on final strain patterns in orogens

5.2.1. Lateral and vertical strain partitioning within the Variscan crust of the Pyrenees

Structural studies performed at the local scale in the Axial Zone led some authors to the conclusion that only south-directed thrusts can be observed (e.g., García-Sansegundo et al., 2011). This interpretation is due to the truncation of the northern part of the Axial Zone by Alpine structures oblique to Variscan ones, especially in its eastern half part (Fig. 3). Our study in the Chiroulet-Lesponne area, where north-dipping thrusts are preserved, allows us to give a more complete view of the Axial Zone. For these reasons we propose in our conceptual model (Fig. 12a) that the Variscan Axial Zone corresponds to a doubly verging accretionary domain (i.e., a narrow orogenic belt) showing south verging thrusts in the southern part, a highly shortened central domain with apparently coaxial deformation and north-verging thrusts on the northern domain. The layered Variscan crust of the Pyrenees is thus characterized by opposite direction of extrusion in response to N-S horizontal shortening. While mid-lower crust laterally flows (lateral escape), the thickening upper crust is affected by vertical (orogen-normal) extrusion (Fig. 12a). The gneiss dome formation is linked to gravitational instabilities within the partially molten mid-lower crust and strain localization that induced the activation of decollement levels, those latter permitting partial decoupling between the two structural domains. The cooling of the crust at ca.

300-290 Ma induced progressive coupling between the two structural domains, as highlighted by the overprint of retrogressive reverse shear zones on high-grade fabrics within gneiss domes (Figs 11 & 12a). In our model, syn-convergence late-Carboniferous/early-Permian volcano-clastic sediments (i.e., the “grey unit” and “transitional unit”, see Pereira et al., 2014) are accumulated into narrow longitudinal basins at the front of these steep thrusts (Fig. 12a) as suggested by recent studies (e.g., Gretter et al., 2015; Lloret et al., 2018). Similar deposition of continental detrital sediments at the front of Gzhelian thrusts was recorded in the Cantabrian Zone (e.g., Pérez-Estaún et al., 1988; Alonso et al., 2009). The transition from deep-sea to intra-continental sedimentation during the Carboniferous-Permian transition also suggests an increasing topography. Thus, the short-lived lateral escape of the mid-lower crust may have not been sufficient to balance overall thickening, which is typical of hot orogen deformation mode (Cagnard et al., 2006; Gapais et al., 2009; Chardon et al., 2009; Bajolet et al., 2015).

In the North Pyrenean Massifs, the deformation appears more heterogeneous than in the Axial Zone with evidence of longitudinal and transverse extension leading to significant crustal thinning and exhumation of the lower crust by the activation of detachment faults (de Saint Blanquat et al., 1990; de Saint Blanquat 1993; Saspiturry et al., 2019). To explain coeval development of extensional structures in the NPM and contractional ones, mostly in the Axial Zone, some advocated the existence of a Late-Variscan NPF separating these massifs (e.g., Arthaud & Matte, 1975; Burg et al., 1994; Matte 2001; Carreras & Druguet, 2014). Following these authors, this supposed - but never observed - lithospheric structure would act as a dextral mega shear zone or a transfer zone. Despite some uncertainties concerning the movement of the Iberian plate at Mesozoic times, a large displacement along the NPF is now widely challenged for the Alpine cycle (Jammes et al., 2009; Tugend et al., 2014; Canérot, 2016; Nirrengarten et al.,

2018, Saspiturry et al., 2019, among others). Therefore, the NPM can be also reasonably considered as the northern continuity of the Axial Zone at Late Variscan times and as a part of the same late-Variscan transpressional tectonic system. In this context, considering that transverse-dominated extension is recorded in the massifs marked by granulite facies metamorphism (e.g., Agly, St-Barthélémy, Castillon, Ursuya, Fig. 3) and that the other massifs recorded only amphibolite facies metamorphism, we suggest that transverse extension is driven by local drastic rheological weakening of the crust. The contrasted structural patterns of the Axial Zone and the North-Pyrenean massifs can be interpreted in terms of lateral strain partitioning due to rheological heterogeneities within the abnormally hot crust during the late-Carboniferous to early-Permian period.

5.2.2. Towards an integrated view of continental mass transfers in the southwestern Variscan realm during Pangea amalgamation

In the Variscan domain of the Pyrenees, vertical strain partitioning occurred between 310 and 290 Ma (e.g., Denèle et al., 2014; Lemirre et al., 2019; Poitrenaud et al., 2020, Fig. 2b) synchronously with large mass transfers that affected the ongoing dismantling Variscan belt under abnormally hot thermal conditions (Fig. 12b). During this short period, folding of the whole Variscan belt led ultimately to the closure of the Iberian-Armorican arc (Cochelin et al., 2017) and the formation of the Cantabrian Orocline (e.g., Weil et al., 2010; Edel et al., 2018). Following the model of formation of the Cantabrian Orocline by bucking of the lithosphere by Gutiérrez-Alonso et al., (2004), shortened areas are supposed to be restricted to the inner parts of the arc (i.e., the Cantabrian Zone) while the outer arc was subjected to widespread extension or wrenching. This model explains lateral strain partitioning in NW Iberia but fails to explain why compression/transpression occurred coevally in many places in the southern realm of the

591 Variscan belt (see the introduction, Fig. 1). We propose that occurrences of transpressive
592 restraining bends in the southern Variscan belt at the late-Carboniferous to early-Permian period
593 reflect lateral strain partitioning and global reorganization of weak continental masses following
594 the ultimate accretion of Gondwana and Laurentia (Fig. 11b). Indeed, the persistence of high
595 geotherms in the Variscan belt (e.g., Fig. 2d, e) due to widespread partial melting and
596 accumulation of magmas in the middle crust after lithospheric delamination (Gutiérrez-Alonso et
597 al., 2004; Buzzi & Gaggero, 2008; Laurent et al., 2017), as exemplified in most of the massifs
598 (Fig. 11b), favored global strain partitioning and triggered extreme mobility of the continental
599 crust. In such a model, three end-members are exemplified (Fig. 12), reflecting how strain can be
600 partitioned within the orogen: i) transpressive restraining bends (Variscan crust of the Pyrenees;
601 Fig. 12a) ii) domains affected by lateral escape combining wrenching and lateral extension
602 (Armorican Massif; Fig. 12c), and iii) those affected by transverse extension and gravitational
603 collapse, (East Massif Central; Fig. 12d). Coeval generation of folds and steep thrusts showing E-
604 W trends in the Cantabrian Zone and the Axial Zone in response to N-S shortening (in present
605 coordinates) in Iberia implies that these two massifs could have formed a single and continuous
606 transpressional restraining bend. The Cantabrian-Axial Zone restraining bend could extend
607 eastward in a Gondwanan autochthonous domain that could correspond to the Mycenian domain
608 belonging to the Paleotethys realm (Stampfli et al., 2013) but such a hypothesis remains uncertain
609 because of the dismembering of the Iberian plate at Cenozoic times (Jolivet et al., 2020). At least
610 two other restraining bends were formed at the Carboniferous-Permian boundary, both
611 southwestward (the Alleghanian belt) and northeastward (Maures – Sardinia – Alpine External
612 Crystalline Massifs) (Fig. 12b). Therefore, it appears that shortening was not only accommodated
613 around bending oroclines as expected by Pastor-Galán et al., (2018) but at a larger scale, within

the entire core of the Pangea supercontinent, coupling lateral extension, wrenching (Fig. 12c), and the formation of highly shortened domains (Fig. 12a, b).

5.2.3. Strain patterns in hot bending orogenic belts and their link to geodynamic evolution

The Western arcuate Variscan belt has been compared to the Pamir West Himalayan syntax (Matte, 1986; 1991). Since oroclinal bending appears to occur in a very different way as the Indian Craton indenter have no equivalent in the weak late-Variscan domain squeezed between the Laurussia and Gondwana cratonic land-masses (Fig. 13), these two belts are indeed characterized by (i) development of crustal-scale strike-slip shear zones on the two branches of a nascent syntax (e.g., Martínez Catalán, 2011; Zhang & Sun, 2020), (ii) strain partitioning processes leading to the exhumation of the deep crustal rock within extensional gneiss domes and syn-convergence lateral and transverse escape of the weak mid-lower crust (Gapais et al., 1992; Stephenson et al., 2001; Martínez Catalán et al., 2014; Gapais et al., 2015; Rutte et al., 2017), (iii) accommodation of deformation over large distances (i.e. more than 600 km wide orogenic belts) in a hot and weak orogenic lithosphere bounded by strong and colder cratonic lithospheres (Fig. 13).

However, the spatial distribution of domains affected by lateral escape, transverse extension, and compression differs in many ways. Above all, it should be noticed that NNE-SSW convergence at ca. 300-290 Ma in the Variscan belt is mostly due to an intracontinental collision (i.e., intra-Pangea) that led to the formation of the Alleghanian belt (Michard et al., 2010; Edel et al., 2018; Figs. 1 & 12b), to the south-west of Western Europe. Thus, the structures that were formed at this period result from the roughly northeastward propagation of stress within the initially NE-SW-trending Variscan belt (Edel et al., 2018 and reference therein). Strain was thus accommodated within a weak lithosphere by bending oroclines, lateral escape, and the formation of

637 compressional/transpressional domains, which are distributed as restraining bends within the
638 whole southern part of the Variscan belt (Fig. 13a). On the contrary, the domains subjected to
639 compression appear as restricted to the edge of the orogen in the Himalayan-Tibet system (Fig.
640 13b). This difference may be explained by the fact that the Variscan belt was affected at ca. 310-
641 300 Ma by orogen-parallel stress (Johnston et al., 2013, Edel et al., 2018) while the Himalayan-
642 Tibet system only recorded orogen-perpendicular stress (e.g., Bosboom, et al., 2014).

643 Syn-convergence gneiss dome formation by transverse extension is common in the Pamir syntax
644 (Fig. 13b), reflecting gravity-driven instabilities within the orogenic plateau (Rutte et al., 2017;
645 Worthington et al., 2020), which may be favored by decoupling between the lower and the upper
646 plate (Bajolet et al., 2015). On the contrary, gneiss dome formation by transverse extension at ca.
647 300 Ma remains rare in the Variscan belt, and occurrences are restricted to the Eastern Massif
648 Central, or, as described in this study, in few NPM. While those from the NPM are similar to the
649 gneiss domes that were developed in the Pamir syntax (i.e., syn-convergence), those from the
650 eastern Massif Central look different. Indeed, this massif only recorded N-S extension at 305-300
651 Ma, leading to the development of widespread sedimentary basins and locally extensional domes
652 (Fig. 13a) (Faure et al., 2009; Ducassou et al., 2019; Vanderhaeghe et al., 2020 and references
653 therein). This suggests a regional evolution with its own dynamics in response to an asymmetric
654 delamination process (Laurent et al., 2017). There, N-S extension could also reflect the influence
655 of the Paleothethys realm to the south (Fig. 12a), which corresponds to a geodynamic free edge.
656 Indeed, roughly N-S extension was recorded within the Paleotethys realm since ca. 300-290 Ma
657 (e.g., Angi et al., 2010; Edel et al., 2014 and references therein). In our model of continuous
658 Cantabrian-Axial Zone restraining bend, longitudinal stretching of the weak lower crust by
659 eastward flow combined to the dextral component of shearing in the upper crust can also reflect

the presence of this free edge to the east (Fig. 12a). Similarly, the propagation of the orogenic front and the orogenic plateau to the west in the Himalayan-Tibet system is controlled by boundary conditions. Indeed, the weak plateau involved in the Pamir syntax is extruded westward as squeezed between the Tian Shan block and the Indian craton (Rutte et al., 2017; Worthington et al., 2020).

To resume, despite both the Variscan and Himalaya-Tibet orogenic systems corresponds to weak domains subjected to bending during ongoing convergence between strong cratonic blocks, they document contrasted finite strain patterns. Specific strain pattern of bending orogenic system in these two domains seems to be related at first-order to initial boundary conditions at the onset of bending such as the direction of stress vs the trend of the earlier belt, the land-mass vs indenter geometry of cratonic lithosphere, and the evolution of free-boundaries. Concerning the southern Variscan belt, it appears that the marked change in the regional stress direction that has occurred at about 310-300 Ma (Edel et al., 2018) was the expression of the self-subduction of the Pangea that led ultimately to its break-up in Permian times (Gutiérrez-Alonso et al., 2008).

Conclusion

The structural patterns observed in the Chiroulet and the Lesponne gneiss domes illustrate how strain was vertically partitioned within a weak layered crust subjected to shortening. This gave rise to first-order structural constraints to retrieve the tectonic and rheological evolution of this part of the Axial Zone in a context of widespread mass transfers and oroclinal bending in the core of the Pangea.

Subjected to a thermal anomaly from the mantle, the lower crust of the Variscan belt was progressively affected by partial melting at ca. 310 Ma. Upward propagation of HT

682 metamorphism induced critical weakening of the crust that was subjected to N-S horizontal
683 shortening. The partially molten mid-lower crust was thus affected by horizontal longitudinal -
684 here eastward - flowing while the upper crust was affected by folding and thickened. Migmatites
685 were partially exhumed due to gravity instabilities, leading to the formation of gneiss domes by
686 extension at their roof. This process was enhanced by the activation of a decollement level
687 located within the kilometer-thick upper Paleozoic marbles. The gneiss domes were then
688 amplified by folding while strain was localized within transpressional shear zones at ca. 290 Ma.
689 These shear zones show “top to the north” (i.e., reverse) kinematics, which is the opposite of
690 well-known transpressional shear zones from the rest of the Axial Zone.

691 By integrating these structural observations at a larger scale, we show that the Axial Zone forms a
692 symmetrical doubly verging accretionary domain where horizontal shortening is accommodated
693 by i) N-S compression yielding northward and southward extrusion of the thickening upper crust
694 by thrusting and ii) horizontal orogen-parallel extrusion of the partially molten lower crust, which
695 is typical of hot orogens. The gravity instabilities were enhanced within the granulitic crust in
696 several NPM, leading to local transverse extension. The evocation of a Late Variscan NPF as a
697 transfer zone or a lithospheric-scale dextral shear zone is not a necessary condition to explain the
698 differences between these neighboring Variscan massifs. As illustrated here, strain was
699 partitioned at the scale of the whole southern part of the Variscides. At the scale of the Variscan
700 belt, we propose that the nonrigid (i.e., weak) Pangea plate was affected by intense continental
701 mass reorganization at the Carboniferous-Permian boundary, leading to the formation of several
702 transpressional restraining bends, like the Cantabrian and Axial Zone bend, coevally with
703 oroclinal bending and continental block rotations. The differences in finite strain patterns
704 between the Variscan belt and other bent hot orogens result from contrasted initial and boundary

conditions, such as the geometry of the strong vs weak lithosphere domains, the orientation of the early belts with respect to the late-compressive stress, and the location of the free edges. In the Variscan belt, the eastward escape of the crust from the Cantabrian-Axial Zone restraining bend could be explained by the presence of a free edge to the east, corresponding to the Paleotethys realm, in a context of Pangea self-subduction.

1341 **Figure captions:**

1342 Figure 1: Structural sketch of the Variscan belt at late Carboniferous times. Source maps from
1343 geodynamic reconstitution are from Franke (2014) for the northern realm of the Variscan belt and
1344 Stampfli et al., (2013) for the southern realm (Alleghanian belt, Alpine Mediterranean domain,
1345 and Paleotethys) with modifications for Corsica, Sardinia, and Maures-Tanneron relative
1346 positions by considering recent paleomagnetic syntheses by Edel et al., (2014, 2018). Directions
1347 of stretching are represented only for the 310-290 Ma period, and were synthesized from (1)
1348 Michard et al., (2010); (2) review from Martínez Catalán et al., (2014); (3) Cochelin et al.,
1349 (2017); (4) Corsini and Rolland, (2009); (5) Carosi and Palmeri, (2002); (6) Casini et al., 2012;
1350 (7) Choulet et al., (2012); (8) Ledru et al., (2001); (9) Echtler and Malavieille (1990); (10) Faure
1351 et al., (1990); (11) Faure et al., (2009); (12) Genna et al., (1998); Rolin and Colchen (2001); (13)
1352 Review from Gapais et al., (2015); (14) Saspiturry et al., (2019); (15) Carreras and Debat (1996);
1353 (16) de Saint Blanquat (1993); (17) Díez Fernández et al., (2012); (18) Escuder Viruete et al.,
1354 (1998); (19) Hernández Enrile (1991). Abbreviations: CZ Cantabrian Zone, CIZ: Central Iberian
1355 Zone, FMC: French Massif Central, AM: Armorican Massif, BM: Bohemian Massif, MN:
1356 Montagne Noire; MT: Maures-Tanneron; CS: Corsica-Sardinia. In the Pyrenees, only the
1357 direction of stretching associated with thrusting is shown.

1358 Figure 2: a) Geological map of the Variscan domains of the Pyrenees, modified from Cochelin et
1359 al., (2017); (b) Available U-Pb ages for metamorphic rocks and granitoids; (c) P-T diagram
1360 showing the P-T paths from the gneiss domes of the Axial Zone, estimations of peak
1361 metamorphism and the range of pressure for emplacement of upper crustal plutons. Aston:
1362 Mezger and Régnier, (2016); Canigou: de Hoÿme de Marien et al., (2019); Bossost: Mezger et

1363 al., (2004); Roc de France: Aguilar et al., (2015); Albères: Vilà et al., (2007). Range of pressure
1364 for pluton emplacement after Autran et al., (1970); Debon et al., (1996); Evans et al., (1998);
1365 Poitrenaud, (2018); Synthetic P-T diagrams representing estimations of the metamorphic peak in
1366 the Axial Zone (d) and the North Pyrenean Massifs (e). Estimates are from Pouget (1989) ; Ayora
1367 et al., (1993); Guitard et al., (1996); Vilà et al., (2007); Mezger and Régnier, (2016) ; Mezger et
1368 al., (2004); Triboulet et al., (2005); Lemirre et al., (2019) in the Axial Zone and from Andrieux,
1369 (1982); Vielzeuf, (1984); Mendia and Gil Ibarguchi, (1991); de Saint Blanquat et al., (1990);
1370 Giró and Alías López, (2007); Tournaire Guille, (2017) ; Siron et al., (2020) for the North
1371 Pyrenean Massifs.

1372 Figure 3: Structural map of the Variscan domains from the Pyrenees, modified from Cochelin et
1373 al., (2017).

1374 Figure 4: a) Simplified geological map of the studied area, modified from Pouget (1984) and
1375 Ternet et al., (1996) with the integration of new field surveys. Cross-sections presented in Figure
1376 6 are localized. A detailed high-resolution geological map is reported in Supporting Information;
1377 b) Structural map of the studied area. Foliation trajectories are inferred from Pouget (1984),
1378 Ternet et al., (1996), and our measurements; A.R.: Aigue-Rouye sub-dome.

1379 Figure 5: Stereogram of poles to foliation or schistosity (i.e., Si and Ss) in the lower, transitional
1380 and upper domains (lower hemisphere; contours=1%). The associated lineations Li or Ls and
1381 kinematics are also reported.

1382 Figure 6: Transverse and longitudinal cross-sections across the Chiroulet and Lesponne gneiss
1383 domes.

1384 Figure 7: Photographs of gneiss, micaschists, and marbles from the Chiroulet and Lesponne
1385 gneiss domes. a) Meter scale sill of porphyritic leucogranite from the Lesponne dome showing a
1386 magmatic foliation Si; b) Well-defined shallowly dipping magmatic foliation Si in diorite from
1387 the Lesponne dome; c) Mineral lineation (Li) defined by the alignment of biotite, sillimanite, and
1388 feldspars within diatexites from the Chiroulet dome. d) Mineral-stretching lineation within
1389 amphibolite boudins in migmatites from the Chiroulet dome; e) Domino-like boudinage in calc-
1390 silicate gneiss at the top of the migmatites from the Chiroulet dome; f) Interference pattern
1391 showing passive reorientation of Li stretching lineation in the hinge of late folds, called Fs
1392 (location: Pic du Midi); g) Typical crenulation of the Si foliation by Ss cleavage in the flank of
1393 regional folds (location: Pic du Midi); h) stretching striae-lineation Ls associated with Ss foliation
1394 within Devonian marbles.

1395 Figure 8: Field photographs of the transitional domain in the southern flank of the Chiroulet
1396 dome: a) Panorama of the southern transition between the lower and the transitional domains of
1397 the Chiroulet dome, located at the top of migmatites. The difference of deformation patterns is
1398 well illustrated, with a poorly disturbed shallowly dipping foliation (Si) in migmatites or Silurian
1399 paragneisses and the same fabric in Devonian series that is intensively folded and sheared by
1400 reverse shear zones; b) Style of deformation within Lower Devonian marbles and
1401 marble/sandstone alternations (location: north-western side of the Lac Bleu), with zooms c) and
1402 d) on folded boudins in these layers; e) sub-vertical mylonitic foliation within marble layers and
1403 asymmetrical boudinage showing south side up kinematics.

1404 Figure 9: Field photographs from the marbles and schists of the upper domain. a) & a') High-
1405 strain fabric in Lower Devonian marbles showing non-coaxial “top to the north” shearing at all
1406 scale (location: Lac Bleu, see also Fig. 8); b) Non-coaxial “top to the north” shearing within low-

1407 grade middle Devonian schists in the southern flank of the Lesponne dome; c) Low-grade shear
 1408 band affecting the diatexites from the Chiroulet dome. Steep C' shears show dextral kinematics;
 1409 d) & d') Post-Variscan reverse faulting showing reactivation of earlier metamorphic fabric (e.g.
 1410 Si foliation) and affecting a Permian andesitic dyke (location: north of the Tourmalet pass).
 1411 Figure 10: Microphotographs from the various rock types of the Chiroulet and Lesponne area.
 1412 The cross-section (a) (i.e., cross-section 2 in Figure 6) represents their localization at various
 1413 structural levels. b) Si foliation in paragneisses, defined by oriented feldspars, quartz, and
 1414 phyllosilicates. Quartz grains show evidence of deformation bands as well as dynamic
 1415 recrystallization by grain boundary migration; c) Si foliation and C/S structures in sillimanite-
 1416 bearing micaschists from the lower domain. Si and C' planes are defined by the alignment of
 1417 biotite, sillimanite, and quartz layers. Evidence of biotite and sillimanite pinning effect in quartz
 1418 grain boundaries underline dynamic recrystallization by grain boundary migration; d) Calc-
 1419 silicate gneiss at the top of the lower domain. Garnet-rich layers are boudinaged and inter-
 1420 boudins are filled by quartz and calcite-epidote veins. Same sample than shown in Fig. 7e; d')
 1421 Zoom on the quartz-vein, where quartz grains are recrystallized by grain boundary migration; e)
 1422 Quartz-rich paragneiss with a core and mantle texture, the core corresponds to garnet and ribbon
 1423 quartz grains (Qtz1) and the mantle to a fine-grained matrix of dynamically recrystallized quartz
 1424 (Qtz2) and muscovite; e') Same quartz-rich paragneiss showing Si/Ss relationships. Note that
 1425 prismatic sillimanites are truncated when reworked by Ss; f) Andalusite-bearing schist where Ss
 1426 schistosity reworked the Si foliation. Andalusites are partially retrogressed into a fine white mica
 1427 and chlorite assemblage; f') Zoom on the same rocks showing inclusions of an early fabric within
 1428 andalusite porphyroclast; f'') Zoom on the same rocks showing dynamically recrystallized quartz
 1429 grains by sub-grain rotation in the matrix; g and g') Chlorite-muscovite bearing Carboniferous

1430 sandstones showing a dissolution pattern. Quartz grains showing recrystallization by bulging in
1431 the matrix and undoluse extinction in porphyroclasts. The cleavage is steeply dipping to the
1432 north. Mineral abbreviations are from Kretz, (1983).

1433 Figure 11: Block-diagrams and synthetic P-T diagrams illustrating the three-stage evolution of
1434 the Chiroulet and Lesponne area. a) The initiation of the thermal anomaly in the lower crust,
1435 leading to the partial melting of the crust. It took place after an earlier stage of deformation D1
1436 that is responsible for the formation of regional NW-SE trending folds. The base of Upper
1437 Paleozoic limestones is reached by the thermal anomaly in the regional synclines, allowing
1438 significant weakening of the upper crust; b) Between 310 and 300 Ma, the mid-lower crust is
1439 partially molten and flows longitudinally under N-S shortening-dominated transpression.
1440 Migmatites are partially exhumed from ca. 4.2 kbar to 2.9 kbar, forming gneiss domes due to
1441 gravity instabilities and strain partitioning. This is marked by the activation of a decollement
1442 level in the thick Devonian marbles. Calc-alkaline plutons intrude the upper crust at this period
1443 while smaller dioritic sheets are stocked at the rheological boundary between infrastructure and
1444 superstructure; c) The cooling of the crust during N-S convergence led to the final crystallization
1445 of magma at 290 Ma, after the emplacement of the leucogranite sheets in gneiss domes. Regional
1446 cooling induced strain localization into steep transpressional shear zones and led to amplification
1447 of the domal shapes by folding. Abbreviation: WS: Wet Solidus.

1448 Figure 12: Illustration of how strain was partitioned within the Variscan belt in map view (b) and
1449 as block-diagrams (a), (c), (d): a) Conceptual model of an opposite direction of extrusion of the
1450 crust under convergence and its relationship with local transverse extension in a few North
1451 Pyrenean Massif.; b) Localisation of the Pyrenees and the highly shortened domains within the
1452 Variscan belt at the Carboniferous-Permian boundary. The Cantabrian Zone and the Pyrenean

1453 Axial Zone form a ca. 100 km wide and 800 km long continuous shortened belt. c) Conceptual
1454 model of lateral escape having taken place in the Armorican massif, after Gumiaux et al., (2004)
1455 and Gapais et al., (2015); d) Conceptual model of transverse extension in the Eastern Massif
1456 Central, after Vanderhaeghe et al., (2020). Further explanation in the text.

1457 Figure 13: Comparison of strain patterns in a context of bending orogenic belts: a) The Variscan
1458 belt during the formation of the Cantabrian orocline and late-orogenic plate reorganization, at
1459 305-295 Ma. The thermal state of the lithosphere is considered following the evidence of ductile
1460 deformations and metamorphism that took place at 305-295 Ma; b) Main tectonic features of
1461 the western edge of the Himalayan-Tibet system. The collision led to westward extrusion of the
1462 orogenic plateau during the formation of the Pamir syntax. Modified from Rolland et al., (2001);
1463 Vanderhaghe & Teyssier (2001); Rutte et al., (2017) & Worthington et al., (2020). Further details
1464 in the text. Abbreviations: CP: Central Pamir; SP: South Pamir, K: Karakorum; MCT: Main
1465 Central Thrust; MBT: Main Boundary Thrust; STD: South Tibetan Detachment.
