Abstract

Metals are essential for life and their concentration and distribution in organisms are tightly regulated. Indeed, in their free form, most transition metal ions are toxic. Therefore, an excess of physiologic metal ions or the uptake of non-physiologic metal ions can be highly detrimental to the organism. It is thus fundamental to understand metal distribution under physiological, pathological or environmental conditions, for instance in metal-related pathologies or upon environmental exposure to metals. Elemental imaging techniques can serve this purpose, by allowing the visualization and the quantification of metal species in tissues down to the level of cell organelles. Synchrotron radiation-based X-ray fluorescence (SR-XRF) microscopy is one of the most sensitive techniques to date, and great progress was made to reach nanoscale spatial resolution. Here we propose a correlative method to couple SR-XRF to electron microscopy (EM), with the possibility to quantify selected elemental contents in a specific organelle of interest with 50x50 nm² raster scan resolution. We performed EM and SR-XRF on the same section of hepatocytes exposed to silver nanoparticles, in order to identify mitochondria through EM and visualize Ag co-localized with these organelles through SR-XRF. We demonstrate the accumulation of silver in mitochondria, which can reach a 10-fold higher silver concentration compared to the surrounding cytosol. The sample preparation and experimental setup can be adapted to other scientific questions, making the correlative use of SR-XRF and EM suitable to address a large panel of biological questions related to metal homeostasis.

Keywords: X-ray fluorescence microscopy; Transmission electron microscopy; Hepatocytes; Mitochondria; Silver.

Introduction

Metal ions are essential for Life. They are required for various processes such as redox-dependent enzymatic reactions, respiration or protein domain structuring. In addition, redox-active free metal ions can induce oxidative stress in cells. Therefore, living organisms tightly control metal ion uptake, intracellular trafficking, storage, and excretion. Although these complex mechanisms, termed homeostasis, are generally well understood for Zn, Fe and Cu in humans, some molecular details remain unclear, in particular the biogenesis of FeS clusters in mitochondria (Beilschmidt et al., 2017). Moreover, disease-related metal overload or environmental exposure to metals or metal nanoparticles disrupt these mechanisms, altering cellular physiology. It is thus of paramount importance to be able to visualize trace element subcellular distribution, *i.e.* down to the organelle level for eukaryote cells.

Various approaches are used to study metal distribution within biological samples, with a large range of sensitivities and spatial resolutions (for review (Decelle et al., 2020)). For large field of view analyses with a moderate sensitivity, two methods exist: Laser-Induced Breakdown Spectroscopy (LIBS) and Laser Ablation Inductively Coupled Plasma Mass Spectrometry LA-ICP-MS (Busser et al., 2018; Greenhalgh et al., 2020; Wiemann et al., 2017). Their micrometer resolution makes them useful for the analysis of tissues. Tens of nanometer resolution can be reached with secondary ion mass spectroscopy (SIMS) and Energy-dispersive X-ray spectroscopy (EDX) in an electron microscope (for a general review on the different methodologies, see (Dressler et al., 2018)). However, their sensitivities do not allow the detection of molecular species at biologically relevant concentrations. The method of choice to analyze the distribution of any element of interest with subcellular resolution, sensitive enough to detect trace elements even in their soluble forms, is X-ray fluorescence (XRF) imaging performed in a synchrotron X-ray nanoprobe (Deng et al., 2017; Fus et al., 2019; Hasna et al., 2019; Tardillo Suárez et al., 2020). As of today, high-resolution 2D elemental images have most often been obtained on whole cells, where the XRF signal from the whole thickness of the cell is summed up, losing the in-depth resolution and consequently the precise distribution within the cell down to the organelle level. In order to overcome this limitation, 3D tomographic XRF imaging should be used (de Jonge et al., 2010; Fus et al., 2019; Yuan et al., 2013). However, the long acquisition time needed to collect a number of projections that allow the accurate reconstruction of the cell volume prevents a routine use of this technique in biology. Possible solutions applied so far consist in either performing 2D XRF imaging over a large sample set, then confirming the findings on a few specimens by acquiring 3D data (Fus et al. 2019), or in coupling

2D XRF on whole cells with other techniques that allow the localization of subcellular compartments. Among the latter, it is worth mentioning organelle labelling followed by fluorescence microscopy (Carmona et al., 2019; Yuan et al., 2013), or TEM observations of cell sections (Chen et al., 2006; Veronesi et al., 2016). In this context, the possibility to perform correlative imaging of cell sections by EM and XRF is highly appealing. This requires the development of sample preparation and measurement strategies that enable the observation of the same specimen with both techniques, in spite of their different experimental requirements. For instance, EM observations rely on heavy metal staining of the biological samples, whereas staining is not recommended for XRF imaging, in particular with metals that would interfere with the XRF signal from the native elements.

Recently, we were able to observe cell sections by both TEM and XRF imaging, in order to follow the entry of Ag(I) ions released from AgNPs into the nuclei of hepatocytes (Tardillo Suárez et al., 2020). In the following, we present a correlative setup to push the combination of these techniques to its utmost performance by performing them on the same cell section, demonstrate that it is able to localize smaller organelles such as mitochondria ($\sim 1 \mu\text{m}$ large), and discuss the details of our sample preparation protocol. The latter is strongly dependent on the scientific question under study: in the case of second row transition metals (as Pd, Ag, Cd) in biological samples, the X-ray excitation energy needed to achieve the highest detection capability for exogenous metal is in the order of 25 keV, much higher than the X-ray energy that would maximize the detection of native trace metals (Mn, Fe, Cu, Zn) and lighter physiological elements (P, S, Cl, K, Ca). Therefore, if the energy is chosen in such a way that the detection of exogenous metal is optimized and its diluted ionic species can be detected, the SR-XRF signal from the native elements would remain weak. Considering this, we used OsO₄ staining to obtain contrast of the cellular membranes in both SR-XRF and EM to visualize cell anatomy. A recent publication described a sample preparation strategy that used tannic acid in order to enhance the contrast in EM while avoiding heavy-metal staining, which proved its effectiveness for the detection of native metals at an X-ray energy of 10 keV (Kashiv et al., 2016).

In this study, the choice of the experimental conditions and of the sample preparation strategy is driven by the need to detect ionic silver species, and is optimized for the study of the fate of second row transition metals in cells or tissues, as for instance in metallodrugs, drug delivery, and nanoparticle research. Ag is a non-physiological metal, but the increasing use of AgNPs as biocides in consumer products and medical devices causes humans to be exposed and to accumulate Ag species in their

bodies. The binding properties of Ag(I) are similar to those of Cu(I), thus Ag(I) can take the place of Cu(I) in Cu-dependent enzymes, thus leading to their inactivation (Ciriolo et al., 1994). We also showed that Ag(I) can replace Zn(II) in the Zn-finger domain of specific transcription factors and thereby impair their activity (Kluska et al., 2020; Tardillo Suárez et al., 2020). The present work exploits the ultimate 50x50 nm² raster scan resolution of a hard-X-ray synchrotron nanoprobe, and in combination with EM, enables the identification of mitochondria to selectively measure their silver content. When hepatocytes are exposed to silver nanoparticles, we demonstrate a higher accumulation of silver in mitochondria compared to the surrounding cytosol, and a mitophagy process can be observed. This case study illustrates the valuable contribution of correlative imaging to the study of the nano-bio interface, by providing a tool to localize and quantify nanoparticles and trace elements at the organelle level. As such, with an appropriate choice of sample preparation and experimental conditions, this methodology can also be used to address a large panel of questions related to metal homeostasis.

Material and methods

Cell culture

HepG2 cells were grown on labtek (Nunc) slides in MEM media supplemented with 10% Fetal Bovine Serum and 1% antibiotics-antimycotic at 37°C in the presence of 5% CO₂. Cells were exposed to 20 nm diameter citrate-coated AgNPs, cit-AgNP (Nanocomposix), or to 90 nm diameter PVP-coated AgNPs, PVP-AgNP (Sigma-Aldrich), at the indicated concentrations of total Ag and for the indicated times. AgNPs were previously characterized (Veronesi et al., 2016). Media and AgNPs were renewed every 24 hours.

Sample preparation for correlative XRF and TEM imaging

Samples were prepared similarly to our recent work (Tardillo Suárez et al., 2020). At the indicated time points, monolayers of HepG2 cells were fixed overnight at room temperature in a 1:1 ratio mixture of 4% paraformaldehyde, 0.4% glutaraldehyde in 0.2 M PHEM pH 7.2 and culture medium, washed in 0.1 M PHEM pH 7.2, and fixed for 30 minutes in 2% paraformaldehyde, 0.2% glutaraldehyde in 0.1 M PHEM pH 7.2, washed in 0.1 M PHEM pH 7.2 and post-fixed in 1% OsO₄ in 0.1 M PHEM buffer for 1 h at room temperature. Cells were then dehydrated in graded ethanol series, and flat-embedded using an Epoxy Embedding Medium kit (Sigma-Aldrich). Sections (200 nm) were cut on a Leica UC7 ultra-

microtome using a DiATOME 35° diamond knife and collected on 50 nm-thick Si₃N₄ grids (Oxford Instruments).

Transmission electron microscopy

Digital images were obtained using a Tecnai G2 Spirit BioTwin microscope (FEI) operating at 120 kV with an Orius SC1000 CCD camera (Gatan).

Nano-XRF data acquisition and analysis

XRF experiments were carried out at the state-of-the-art hard X-ray nanoprobe beamline ID16B at the ESRF (Martínez-Criado et al., 2016). ID16B can be operated in 2 different regimes optimized either for the energy resolution (required for X-ray diffraction and absorption spectroscopy) or for the photon flux (for XRF mapping and holotomography). In the high flux mode used for this experiment, the monochromaticity of the beam ($\Delta E/E = 10^{-2}$) is given by multilayer KB mirrors and the photon flux is in the 10^{11} photons/s range. The incoming photon energy was set at 29.6 keV and the beam was focused down to 55x65 nm² using Kirkpatrick-Baez mirrors. The fluorescence emission from the sample was recorded using two 3-element Silicon Drift Detectors (SDD) arrays positioned at 13° from the sample. High resolution maps were recorded at room temperature, raster scanning the sample in the X-ray focal plane with 50x50 nm² step size and 500 ms to 1 s dwell time/pixel.

Hyperspectral images were analyzed using the PyMCA software package (<http://pymca.sourceforge.net/>)(Solé et al., 2007). The detector response was calibrated over a thin film multilayer sample from AXO (RF8-200-S2453). XRF data were energy calibrated, normalized by the incoming photon flux, and batch-fitted in order to extract spatially resolved elemental concentrations, assuming a biological matrix of light elements and density of 1 g.cm⁻³ according to NIST standards (<https://physics.nist.gov/cgi-bin/Star/compos.pl?matno=261>). Quantitative results are reported in areal density units (ng/mm²) to facilitate the comparison with previous works. However, considering that in the present case the sample thickness is known, mass fractions (w/w) can simply be retrieved by dividing areal densities by the assumed sample density (1 g.cm⁻³) and by its thickness (200 nm).

Results and discussion

Implementation of correlative TEM and XRF microscopy

Recently, we successfully used XRF on cell sections for the analysis of Ag transformations and distribution within hepatocytes exposed to AgNPs (Tardillo Suárez et al., 2020). In the current study, the

methodology was extended to be able to pinpoint the trace element content in the organelles of interest. Cells were grown on standard labtek supports that were used for chemical fixation using paraformaldehyde/glutaraldehyde. This method is a good compromise to preserve the intracellular content in comparison to alcohol-based fixation (Jin et al., 2017; Sanchez-Cano et al., 2017). Sample processing was based on classical cell resin-embedding preparation protocols. However, to avoid parasitic signals, all heavy metals classically used to stain and enhance contrast in the sample (for instance U and Pb) were avoided, with the exception of OsO₄. The latter is necessary to preserve the cellular ultrastructure by reacting with the lipids in the membranes. Moreover, OsO₄ also provides contrast of cellular membranes both in TEM and in XRF, thanks to the electron scattering and an X-ray absorption properties of the heavy Os atoms. The effect of the OsO₄ treatment on the elemental content of fixed cells was estimated empirically, by comparing the elemental distributions of metals by XRF imaging in cells exposed to citrate-coated AgNPs for 72 h, then chemically fixed with or without OsO₄ post-fixation. The average elemental composition per cell, estimated over three cells per condition, are reported in **Table S1**. The trace element contents in the cell area were measured, and showed that only in the sample post-fixed with OsO₄ it is possible to distinguish basal Fe from the background, and that the native Cu content is double that of the Os-free sample. It is not possible however, to determine the amount of native Zn in the presence of Os, because of the overlap of the X-ray emission lines of the two elements (**Fig. S1** and **Table S1**). Moreover, the cytosolic concentration of molecular Ag(I) determined by XRF mapping is twice as high in the case of hepatocytes prepared with Os in comparison to cells prepared without, 0.22± 0.04 ng/mm² versus 0.11 ± 0.02 ng/mm², respectively (**Fig. S1**). Os fixation is therefore crucial to retain the soluble metal ion complexes inside a cell and its various compartments. A possible explanation resides in the fixation mechanism known for OsO₄, which stabilizes the cellular membranes by cross-linking their phospholipidic chains (Wigglesworth, 1957), resulting in the retention of labile ions by cellular compartments. For this reason, and because Os provides contrast of the cellular membranes in XRF, enabling the identification of organelles and a direct comparison with TEM micrographs, we introduced OsO₄ fixation in the optimized sample preparation protocol. However, whenever the determination of Zn content is crucial for the scientific question under investigation, and if the X-ray beam energy is above the Os L_{III}-edge excitation threshold (10.87 keV), another preparation protocol should be applied, by substituting OsO₄ with another oxidant acting on lipids for example. Alternatively, the X-ray energy could be set between 9.66 keV (Zn K-absorption edge) and 10.87 keV,

in such a way that only Zn atoms are excited, whereas Os atoms are not. This last option would not be suitable for the present study, where the energy has to be optimized for the excitation of Ag core-levels (above 25.51 keV) in order to achieve the highest sensitivity to this metal, but would be pertinent for studies focused on 1st row transition metals. Ideally, the opportunity to map a sample area both at high energy (above the Ag K-edge) and at ~10 keV would allow the most efficient detection of the exogenous metal, of the native trace elements, and a more efficient detection of the lighter physiological elements. This option is often not compatible with the duration of a synchrotron experiment, and a single excitation energy has to be chosen, leading to the choices mentioned above.

Thin sections produced by ultramicrotomy were deposited on Si₃N₄ EM grids comprising a square window 500 µm wide and 50 nm thick that are suitable for both EM and XRF imaging. The surface area is limited, which limits the number of cells in the window but facilitates the retrieval of the areas of interest. The Si₃N₄ EM grid was first scrutinized by TEM to identify cells with organelles and/or markers of interest inside. The position of the chosen cells was roughly found by the optical microscope on the ID16B beamline. Fast XRF mapping at low dose deposition was performed at low spatial resolution with 1x1 µm² step size and 100 ms dwell time to confirm the location of the cells of interest by observing the Os signal. The latter also provided shadows of the organelles and thus gave confidence in the proper retrieval of the area of interest. Fast scans also limited the radiation damage. In a second step, XRF mapping at high-resolution (down to 50x50 nm² step size and with a dwell time of 500 ms per point or more) was performed to obtain high quality XRF data in terms of both spatial resolution and sensitivity. These maps were acquired on an area of the order of 10x10 µm² in order to limit the acquisition time to a few hours.

A section of an HepG2 cell exposed for 6 hours to 50 µM cit-AgNPs was sequentially imaged by TEM (**Fig. 1A**) and then XRF (**Fig. 1B-C**). The low-resolution TEM image of the complete cell section revealed the different cellular compartments, among which the nucleus is the largest, and which can also be identified on the XRF map of Os L α since the nucleus is not penetrated by this metal species. As a proof of principle, the TEM image enabled to observe electron dense objects (red and orange arrows) that can be attributed to Os deposits (orange arrows) and AgNPs in endosomes or lysosomes (red arrows) thanks to the extraction of the specific elemental maps of Os and Ag, respectively (**Fig. 1D-E**). Therefore, such a correlative use of TEM and XRF enables the simultaneous determination of the ultrastructure and of the content of the elements of interest in the interior of a cell. Such information can also be

retrieved using TEM coupled to energy dispersive X-ray spectroscopy. However, the sub-ppm sensitivity of XRF is necessary to detect trace metal amounts of a few attograms (10^{-18} g) per pixel (Veronesi et al., 2016).

Fig. 1. Correlative TEM and XRF for the identification of Os deposits *versus* AgNPs. Analysis of a 200 nm section of a HepG2 cell exposed to 50 μ M cit-AgNPs for 6 h. (A) TEM image with orange and red arrows pinpointing areas of interest showed in XRF images. (B) Os and (C) Ag areal density maps in false colors for the same section obtained from XRF data. XRF acquisition was done with a pixel size of 100x100 nm². TEM micrograph overlayed with Os (D) and Ag (E) XRF maps. All scale bars correspond to 2 μ m.

Sensitivity and spatial resolution of TEM-XRF in comparison to STEM-EDX

In a recent study, we considered two different chemical forms of silver: i) AgNPs, always found in endosomes and lysosomes, in a partially transformed or in their pristine form, and ii) molecular Ag(I)-thiolate species that were found, at least, in the cytosol or in nuclei (Tardillo Suárez et al., 2020). However, we expect to be able to disclose the distribution of cytosolic Ag between the different organelles such as mitochondria, endoplasmic reticulum or Golgi apparatus. It is frequently assumed that Ag(I) can accumulate in mitochondria *via* the Cu(I) uptake pathway that remains elusive at the molecular level (Cobine et al., 2006). A section of HepG2 cells exposed to 25 μ M PVP-AgNPs for 24

hours was inspected by TEM (**Fig. 2A**). We could easily identify the nucleus surrounded by mitochondria (green rectangle in **Fig. 2A** and zoom-in in **Fig. 2B**). The area rich in mitochondria (red rectangle) was selected for further analysis by XRF, with the aim to compare Ag concentration in mitochondria and cytosol. These acquisitions were done at a raster scan resolution of 50x50 nm² to obtain detailed images of mitochondria. Osmium enabled to confirm the location of mitochondria with respect to the nuclear membrane (**Fig. 2C**). Very interestingly, the Ag areal density map in false color (**Fig. 2D and 2E**) revealed a slightly higher concentration of Ag within mitochondria compared to the surrounding cytosol: 0.08 ng/mm² in average inside mitochondria *versus* 0.05 ng/mm² in the cytosol, after background subtraction and fitting of the XRF signal integrated over the two different cellular compartments. This demonstrates that our analytical protocol is able to map the subcellular distribution of highly diluted dissolved soluble silver species in selected compartments.

Fig. 2. Ag(I) accumulation in mitochondria in HepG2 cells exposed to AgNPs. (A) Large TEM field of view with several cells visualized from a section of HepG2 cells exposed to 25 μ M PVP-AgNPs for 24 hours. (B) Close-up view of the cell of interest, green rectangle in A. (C) Os and (D) Ag areal density maps represented in false-colors of the region of interest, red rectangle in A and B. Red arrows pinpoint the same mitochondria in C and D. (E) TEM micrograph overlaid with Ag XRF map. XRF acquisitions were done with a pixel size of 50x50 nm².

Control cells (*i.e.* not exposed to AgNPs) were also imaged using this correlative approach (**Fig. 3**). A field presenting many mitochondria was identified by TEM (**Fig. 3A**, red rectangle) and then scanned by XRF (**Fig. 3B-E**). The Os map again revealed mitochondria shadows (**Fig. 3B and 3F**, red arrows) and the Ag map showed only noise signal (**Fig. 3C**). The distribution of some native elements in the same field of view is also shown: Ca (**Fig 3D**) shows a contrast between the interior and the exterior of the cell, meaning that this native element is detected. However, the high excitation energy chosen to optimize the detection of Ag, and the absorption by the air of the emitted Ca K α fluorescence at 3.69 keV, do not allow the quantification of the fine variation of its intracellular concentration. In contrast, the distribution of Fe (**Fig 3E**), as a consequence of the higher energy of the XRF emission of this element (Fe K α fluorescence at 6.40 keV), shows a significant signal compared to the background and variations in the local concentration can be correlated with the cell's anatomy. However, none of the native element distributions enabled the localization of mitochondria, for which both Os staining and TEM imaging were necessary.

Altogether, our data demonstrates that the correlative methodology we have developed can efficiently and simultaneously detect AgNPs, soluble silver species, and subcellular compartments. This enabled us to detect minor differences in terms of silver accumulation within a specific organelle, in this case the mitochondria.

Fig. 3. Control cells analysis. (A) TEM image of the region of interest in a section of HepG2 cells non-exposed to AgNPs. (B) Os, (C) Ag, (D) Ca and (E) Fe areal density maps in false colors for the same region of interest, red rectangle in A. Mitochondrial shadows are pinpointed with red arrows in B. Black arrow pinpoint a vesicle containing Os deposit as seen by TEM (A). (F) TEM micrograph overlaid with Os XRF map. XRF acquisition was done with a pixel size of 50x50 nm².

To compare this multimodal approach with conventional STEM-EDX, a field comprising part of a nuclei, cytosol, a mitochondria (red arrow), and a lysosome containing AgNPs and transformed AgNPs (orange arrow) was imaged by STEM (**Fig. S2A-B**). EDX analysis showed that only electron dense spots within the lysosome present a significant Ag signal (**Fig. S2C-D**), confirming that these were AgNPs or dissolving AgNPs. The mitochondria, the cytosol and the nucleus did not display a detectable Ag signal

by EDX, while synchrotron nanoprobe XRF enabled us not only to detect molecular Ag(I) species found in these three compartments but also to precisely quantify local Ag(I) concentrations and thus rank them according to their Ag(I) accumulation: the highest is found in mitochondria, followed by the cytosol and finally the nucleus. This is an empirical demonstration of the higher sensitivity of SR-XRF with respect to STEM-EDX, as already reported in the literature (Decelle et al., 2020). In order to explain the fundamental reasons for this difference, we have to consider that both STEM-EDX and SR-XRF rely on the physical principle of the photoionization of core electrons of the atoms in the specimen, followed by the emission of characteristic X-rays due to their radiative de-excitation. The two techniques differ in the choice of the probe: synchrotron X-rays in SR-XRF, electrons in STEM-EDX. The observed higher sensitivity of the former most probably depends on the higher efficiency of the excitation operated by X-rays with respect to electrons. The theoretical description of these phenomena could help elucidate the difference between the sensitivity of the two techniques, as in the literature such a comparison relies only on empirical basis. These calculations are beyond the scope of this work, and a discussion meant to set the basis for it, is reported in the SI.

In conclusion, the combined ultrastructural imaging and trace element quantification obtained by the correlative TEM and XRF imaging approach provides additional information with respect to the STEM-EDX method.

XRF offers a high dynamic range

Together with sensitivity to low concentrations, the dynamic range is an important parameter in elemental imaging, in particular for elements that are present in both their crystalline form (e.g. nanoparticles) and as soluble molecular complexes. An example in biology is Fe, which is stored in a mineral form in ferritin and exists also as an enzyme co-factor. The dynamic range is also crucial in the determination of the intracellular fate of AgNP, where both crystalline and soluble silver need to be detected. Indeed, AgNPs are endocytosed and dissolved within endo-lysosomes into Ag(I) species that are then distributed throughout the cell (Veronesi et al., 2016). XRF is quantitative over at least 5 orders of magnitude, as shown in **Fig. 4**. XRF rendering using a linear scale ranging from 0 to 80 ng/mm² only highlights the presence of Ag-rich spots in vesicles, attributable to internalized AgNPs, together with a much weaker signal throughout the vesicles, most probably due to Ag(I) released from the NPs in the acidic lysosomal environment (**Fig. 4B, red arrows**). However, the visualization of Ag in the same area

with a scale ranging between 0 and 0.5 ng/mm² highlights the presence of a much weaker signal (< 0.1 ng/mm²) in the cell cytosol, not visible in the previous representations (**Fig. 4C**). Finally, the use of a logarithmic-scale representation of Ag distribution highlights at a glance the presence of all Ag species, regardless of their concentration (**Fig. 4D**). The detection of these species is made possible by the choice of the excitation energy, optimized for the photoexcitation of silver core electrons (Ag K-edge), and by the high photon flux of 10¹¹ photons/s provided by the nanoprobe in the chosen experimental conditions.

Fig. 4. False-color representation of Ag distribution in hepatic cells exposed to 50 µM citrate-coated AgNPs for 72 h. (A) Os (green) and Ag (red) two-color map highlights the subcellular compartments and the presence of Ag-rich vesicles (red arrows). (B) Ag distribution visualized using a linear color scale ranging between 0 and 80 ng/mm². (C) Ag distribution visualized using a linear color scale ranging between 0 and 0.5 ng/mm². (D) Logarithmic-scale representation of Ag distribution in the same area (0-100 ng/mm²). Red arrows pinpoint endo-lysosomes containing partially transformed AgNP. n, N and c stand for nucleus, nucleolus and cytosol, respectively. Scale bars correspond to 2 µm.

This example demonstrates that XRF nano-imaging has the unique advantage to be able to detect simultaneously metallic nanoparticles and soluble metal complexes, providing high detection performances over a very large concentration range. It also highlights the importance of the choice of the visualization parameters to reveal the presence of all signals detected by the hyperspectral imaging technique. Finally, the high sensitivity and dynamic range of SR-XRF are interesting to correlate with EM ultrastructure imaging only because progress has recently been made in its spatial resolution which is now getting closer to that of EM.

Catching events, the example of mitochondrial Ag overload-induced mitophagy

One main advantage of a single-cell, imaging-based analysis method compared to a bulk quantification approach is the possibility to identify specific events that occur rarely, but that are crucial to completely

understand a biological process. Moreover, an imaging method can also dissect a whole process, by visualizing the whole cascade of events. In the data acquired on HepG2 cells exposed to 25 μM PVP-AgNPs for 72 hours, a mitochondrion located inside a double membrane vesicle was visualized by TEM (**Fig. 5A**, red arrow). This is clearly a mitochondrion that has been engulfed in an autophagosome, illustrating the triggering of a mitophagy process (Ding and Yin, 2012). The Ag areal density map of this region revealed a high Ag content in the mitochondrion located in the autophagosome (**Fig. 5B-C**, red arrow). Indeed, the value was in the order of 1 ng/mm^2 , to be compared to the typical 0.04 to 0.14 ng/mm^2 range observed in normal mitochondria in the various tested conditions. Therefore, this particular mitochondrion accumulated 10-times more Ag than healthy mitochondria. This example highlights the importance of associating quantitative elemental distributions to high-resolution structural observations, since it revealed that the observed mitophagy is likely due to Ag overload. Current cell analyses assume comparable Ag(I) molecular species uptake for a type of organelle and previous studies showed directly or indirectly a significant Ag(I) entry into mitochondria (Vest et al., 2013). However, our data showed a broad variability in silver amounts accumulated in each of the mitochondria. Interestingly, close to this mitochondrion undergoing mitophagy, Ag hot spots could be observed in **Fig. 5B-C** (red pixels), corresponding to AgNPs and/or transformed AgNPs, as confirmed by the TEM micrograph (**Fig. 5A** and **5C**). It is thus possible to imagine that mitochondria close to endosomes and/or lysosomes containing dissolving AgNPs undergo a massive accumulation of Ag that leads them to collapse and be degraded by mitophagy.

Fig. 5. Ag-overload induce mitophagy. (A) TEM image from a section of HepG2 cells exposed to 25 μM PVP-AgNPs for 72 hours. (B) Ag areal density map in false colors of the region of interest, red rectangle in A. (C) TEM micrograph overlaid with Ag XRF map. The red arrow pinpoints the same mitochondria in A, B and C. XRF acquisition was done with a pixel size of $50 \times 50 \text{ nm}^2$.*

Conclusions

In the current study, we have developed correlative TEM and hard X-ray nanoprobe XRF imaging on the same cell section, by using a preparation protocol for classical cellular EM, modified to use OsO₄ as the only heavy metal staining. Indeed, OsO₄ is required both to protect trace elements from partial leakage out of the cell and to visualize cellular membranes where Os accumulates. This methodology has been optimized on sections of 200 nm. This thickness was chosen to provide, on the one hand, TEM images with enough detail to identify the different organelles, and on the other hand, high enough XRF signal for trace element mapping. The synergistic use of the two techniques on the same sample enables to map selected elemental distributions at the organelle level. The quality of the data that can be obtained, as well as the sensitivity and the accuracy of the quantification, were evidenced in this study by the analysis of Ag(I) molecular species partitioning between mitochondria and the surrounding cytosol in hepatocytes that have been exposed to AgNPs. These experiments proved that, following AgNP dissolution into Ag(I), molecular species containing Ag(I) can enter mitochondria. The entry could be due to the recruitment of Ag(I) by the Cu(I) mitochondrial uptake pathway. However, this process seems rather not controlled by the cell since mitochondrial uptake of Ag(I) can lead to a mitochondrion with ten times higher level than all others, ending up into an autophagosome. This event was observed close to a lysosome containing dissolving AgNPs. One can hypothesize that Ag(I) uptake is mainly driven by localization effect and no other control mechanism exists. All these data bring insight in the context of AgNP fate and toxicity in the liver, and demonstrate the usefulness of the method.

From a more general standpoint, with the opportune choice of the X-ray excitation energy and sample preparation protocol, this method can be extended to the study at the subcellular level of mechanisms involving other trace elements, such as iron or copper homeostasis. In this study, we chose a beam energy of 29.6 keV, which is optimal for Ag mapping but not for the detection of the lighter, native metals such as Cu or Zn, for which a lower excitation energy is required to obtain the highest sensitivity. Moreover, the Os L edge can overlap with some elements of interest, for instance Zn. To overcome this limitation, the sample preparation could be modified by replacing OsO₄ with RuO₄ (Swartzendruber et al., 1995). Finally, it is worth mentioning that the ESRF, as well as other synchrotrons world-wide, recently upgraded their storage ring to obtain enhanced performances. On the beamline ID16B, this originates a 10-fold increase in the photon flux, which will enable faster acquisition time in the ms/pixel range, provided that XRF detectors can run in this regime. Reducing the acquisition time will also be

necessary to preserve the samples from beam-induced damages. Combined to the pre-screening of the samples through TEM and pre-identification of the regions of interest, SR-XRF imaging can provide elemental compositions with unrivalled sensitivity, resolution, and acquisition time.

In conclusion, the correlative TEM and XRF imaging approach presented here consists in optimizing the implemented use of the two techniques, commonly used separately, to obtain elemental distribution maps enriched with their ultrastructural context, which is crucial for the study of metal homeostasis mechanisms or to understand the fate of non-physiological metals.

Conflicts of interest.

The authors have no conflicts of interest to disclose.

Acknowledgements

The authors acknowledge the ESRF for providing beam time on the beamline ID16B-NA. This work used the platforms of the Grenoble Instruct-ERIC Center (ISBG: UMS 3518 CNRS-CEA-UGA-EMBL) with support from FRISBI (ANR-10-INSB-05-02) and GRAL (ANR-10-LABX-49-01) within the Grenoble Partnership for Structural Biology (PSB). The EM facility is headed by Guy Schoehn and supported by the Rhône-Alpes Region, the Fondation Recherche Medicale (FRM), the fonds FEDER and the GIS-Infrastructures en Biologie Sante et Agronomie (IBISA). This project received funding from GRAL and Arcane Labex, a programme from the Chemistry Biology Health (CBH) Graduate School of University Grenoble Alpes (ANR-17-EURE-0003). This research is also part of the LabEx SERENADE (grant ANR-11-LABX-0064).
