Introduction

Unlike the microelectronics field where Transmission Electron Microscopy (TEM) is extensively used in failure analysis, process development, and metrology [1], in the photovoltaic field TEM is rarely used because materials such as amorphous hydrogenated materials [2][3] or perovskite structures are very unstable under the electron beam, posing great challenges and requiring special care in establishing characterization methodologies. Local information provided by TEM techniques thanks to their high spatial resolution could provide a better understanding of physico-chemical mechanisms and therefore lead to improved manufacturing processes to have more efficient solar cells. The purpose of this article is therefore to report, detail and limit as far as possible the electron beam irradiation damage in order to have a characterization as relevant as possible. The aim of the article is to propose methods that can be used on standard microscope with no major instrumental modification. We propose a methodology to study amorphous aluminum oxide / amorphous hydrogenated silicon nitride ($\text{a-AlO}_x/\text{a-SiN}_x\text{:H}$) passivation stacks deposited respectively by Atomic Layer Deposition (ALD) and Plasma Enhanced Chemical Vapor Deposition (PECVD) on p-type crystalline silicon (c-Si). In c-Si solar cell, passivation layers are used to preserve the electronic properties by limiting the surface recombination. This dielectric passivation stack has allowed to move from the Al-BSF (Aluminium Back Surface Field) device to the PERC (Passivated Emitter and Rear Cell) device. Nowadays, $\text{a-AlO}_x/\text{a-SiN}_x\text{:H}$ is also a good candidate to passivate the rear side of two-terminal perovskite/silicon tandem cells [5]. The well known thermal oxidation (a-SiO_2) of the c-Si surface carried out at temperature between 800-1000°C is no longer accepted in terms of industrial thermal budget and therefore has to be avoided in order to decrease the cell process cost. Deposited at temperatures between 200°C and 300°C, ultrathin a-AlO_x provides chemical passivation by reducing c-Si dangling bonds at the interface and offers a field effect passivation mainly through intrinsic negative fixed charges which drastically decrease the surface recombination velocity. The control of these negative fixed charges remains difficult because their origin is believed to be diverse (vacancies, interstitial atoms, coordination, traps) [6][7][8]. $\text{a-SiN}_x\text{:H}$ is an anti-reflective layer, as well as an hydrogen reservoir which improves the chemical passivation at the c-Si/ a-AlO_x interface. Moreover it acts also as a capping layer improving the thermal and chemical stability of a-AlO_x . In this work, in order to understand the electron-beam sensitivity during Scanning

TEM coupled with Electron Energy Loss Spectroscopy (STEM-EELS), we carry out a detailed electron-beam irradiation damage study of the c-Si/a-AlO_x interface. The importance of the electronic dose and the accelerating voltage in the formation of this damage will be argued. Useful information will be given to limit the dominant irradiation damage by modifying STEM-EELS acquisition parameters. Finally the composition of the interface will be analyzed thanks to these optimized analysis parameters and then discussed.

Material and methods

The passivation stack composed of a-AlO_x and a-SiN_x:H was symmetrically deposited on a polished crystalline silicon (c-Si) test cell (also called lifetime samples) by Lebreton *et al.*[9]. Lifetime samples are intended for research and development purposes, the rear side of the studied solar cell architecture being processed on both sides of the wafer. The p-type (100) c-Si Float Zone (FZ) substrate was double-side polished, with a resistivity of 3 Ω.cm and a thickness of 280 μm. After dipping the latter into 5% HF, a-AlO_x deposition using Trimethylaluminum (TMA) and water was carried out by Thermal-Drift Atomic Layer Deposition (TD-ALD). For these samples, the thermal drift conditions mean that the deposition is carried out when the temperature of the substrate increases from 200°C to 250°C during 60 ALD cycles (corresponding to a layer of 6 nm). This variation of the temperature during deposition enables the surface recombination velocities below 10 cm.s⁻¹ (typical value required to have solar cells with a power conversion efficiency higher than 20% [10]) and prevents the formation of blisters (defects studied and characterized by Lebreton *et al.* [11]) that degrade the optical and electrical properties of such a passivation stack. The as-deposited a-AlO_x layer brings a chemical passivation of the c-Si surface, the advantage of a-AlO_x is that it also provides a field effect passivation which is activated by an annealing step in a forming gas atmosphere during 30 minutes at 380°. The a-SiN_x:H capping of 75nm is performed by Plasma Enhanced Chemical Vapor Deposition (PECVD) at 420°C and is followed by a final annealing step done at 380°C for 20 minutes which simulates an electroplating metallization step [12].

The structure of the interface in such stack needs to be characterized with a local investigation

technique, transmission electron microscopy (TEM) has been chosen in this study to complete other macroscopic characterizations [11][13]. TEM requires specific sample preparation to get electron transparent lamella. Using Focused Ion Beam (FIB), these lamella were lifted out as cross sections through the epi-layer using an adaptation of the Schaffer *et al.* method [14]. A FEI Helios NanoLab 600i was used to perform the lift-out technique that allows to have the least damage of the sample and to have the best atomic resolution in STEM and HRTEM. The first step of the FIB preparation is the orientation of the sample to have the desired [110] zone axis to observe low index family planes edge on. Then, a platinum layer was deposited first by using the electron beam and then by using the ion beam. Indeed, electron beam induced deposition is less energetic than ion beam induced deposition and allows to preserve the sample surface. Initial wedge-milling was performed using a gradual decrease of gallium ions voltage from 30 kV, 16 kV, 8 kV to 5 kV with the cleaning cross section (CCS) pattern. Compared with the classic lift-out FIB pre-milling described by Bals *et al.*[15], which uses parallel pre-milling with a constant voltage at 30kV, the wedge-milling that we used allows to preserve the area of interest against amorphization [16] and to limit gallium implantation by decreasing the tension at each milling step. The thinning was carried out in staircase profile, each voltage corresponding to a step of the stair ; this allows us to see the progress of the thinning. Once the 5 kV of ion beam was reached, we used a 5kV electron beam during milling to monitor the thinning process. A contrast reversal allowed us to monitor the thickness of the lamella. The last thinning steps were done at 2 kV and 1 kV with Rectangular Cross Section pattern and the thickness monitoring with electron beam at 2 kV. This technique is much longer (around 4 hours) than the classical one but gives high quality and thin (≤ 70 nm) electron transparent area over 6 μm length for STEM analysis. This method has been chosen because FZ silicon used as a substrate in this study is more likely to be contaminated than Czochralski silicon. Indeed, the increased purity of the material leads to a higher sensitivity to contamination. Thus, this is a real challenge both for preparation (ion beam) and for observation (electron beam and carbon contamination).

A JEOL ARM200F aberration corrected STEM with a probe size of 0,1 nm was used for chemical imaging and spectroscopy. The real probe size is however larger than this theoretical one due to the probe shape and some lateral extension within the thin lamella, especially throughout the amorphous

layer. STEM-HAADF images were taken before and after STEM-EELS acquisition to check if there was any change in contrast or in the structure due to electron beam damage. Electron energy loss spectroscopy (EELS) was performed with a GIF Quantum ER detector in STEM mode, using a 30 mrad convergence and 39 mrad collection angle. Energy resolution was measured at the full width at half maximum of the zero loss peak (ZLP) to be between 0.4 and 0.5 eV for all our experiments. A dispersion of 0.05 eV/ch was chosen to study the Energy Loss Near-edge fine Structures (ELNES) of Al $L_{2,3}$ and Si $L_{2,3}$ edges. This dispersion was chosen to track any modification of the silicon oxidation number that could be deduced from the modification of the Si $L_{2,3}$ edges ELNES signal. The a- AlO_x electron beam sensitivity forced us to study the $L_{2,3}$ -edges rather than the high energy K-edges of aluminium which would imply longer exposure times and consequently more damage to the interface and the passivation stack. The EELS spectra were recorded by using DualEELS and Spectrum Image (SI) acquisitions. DualEELS is a system directly implemented in the EELS spectrometer which allows the acquisition for each pixel of two energy loss spectra from different energy ranges. We used it in two different ways, either by recording ZLP and plasmon peaks on the first energy range and Al $L_{2,3}$ -edge and Si $L_{2,3}$ -edge on the second range to deconvolve spectra or by recording Al $L_{2,3}$ -edge and Si $L_{2,3}$ -edge on the first range and the O K-edge on the second range to study the evolution of the fine structures of these edges which are more than 400 eV apart (as presented in Figure 3). Spectrum image [17] is a 3D data set i.e at each x-y position (navigation space) which forms a pixel of the image an entire spectrum is stored along the z axis (signal space) e.g., if we sum over several pixels in a area containing one material (like silicon) it will increase the signal-to-noise ratio providing better definition of the considered ELNES. During data treatment, Principal Component Analysis (PCA) was applied to extract the main components of our SI which were hidden by noise using the temDM MSA software routine for DigitalMicrograph available at www.temdm.com. Indeed, PCA is a well known multivariate statistical analysis allowing the isolation of meaningful variations from noise. The profiles and maps displayed on Figure 2 and Figure 3 were obtained thanks to a processing tool included in DigitalMicrograph called Multiple Linear Least-Squares (MLLS) fitting [18]. The latter routine aims at decomposing the considered spectrum as a linear sum of theoretical or experimental reference spectra. As the shape of the c-Si and a- AlO_x ELNES of our EELS measurements had the

same characteristics as the literature references, we have directly taken the references in our data. Furthermore, MLLS fitting bring better results when the reference data are recorded with the same acquisition conditions as those applied to the studied materials.

Results

As explained before, the goal of this article is to analyze the c-Si/a-AlO_x interface from a passivation stack a-AlO_x/ a-SiN_x:H over c-Si which is highly sensitive to the electron beam. Previous High Resolution TEM (HRTEM) experiments (not shown here) indicated a high sensitivity of a-AlO_x and a-SiN_x:H layers. Indeed, a-AlO_x can crystallize into γ -Al₂O₃ under the electron beam, as determined by many authors [2][3][19] and a-SiN_x:H can undergo huge morphological modifications with the formation of bubble-like defects as reported by Liu *et al.* [20]. It was thus very difficult to have faithful HRTEM images of the stack and the c-Si/a-AlO_x interface, even by limiting the electron dose. However, we can see in [Figure 1.a](#)) that the a-SiN_x:H and the a-AlO_x/a-SiN_x:H interfaces are very sensitive even when using STEM. Indeed, in this image acquired at 200 keV, some parts of the a-SiN_x:H bulk started to be extensively damaged and it also started to loose its adhesion with a-AlO_x under the beam while c-Si/a-AlO_x interface and a-AlO_x remained intact. That is the reason why, we took this image as a reference to measure c-Si/a-AlO_x interface and a-AlO_x thickness.

Figure 1: STEM-HAADF images before and after EELS Spectrum Image recording. a) STEM-HAADF before EELS. b) STEM-HAADF after STEM-EELS at 200keV. c) STEM-HAADF image after STEM-EELS at 80 keV.

From the latter image (Figure 1.a)) the thickness of a-AlO_x was measured to be 6.2 nm as expected from the deposition process. We were also able to measure an interfacial layer contrast of 1.3 nm at the c-Si/a-AlO_x interface meaning that there is the formation of another chemical compound between c-Si and a-AlO_x . STEM-EELS studies were carried out to explain this contrast and the acquisition parameters of the spectra had to be adjusted to take the beam sensitivity into account. We started STEM-EELS experiments at an acceleration voltage of 200 keV, spectra were acquired in the black box area represented in the drawing of Figure 1 thanks to the EELS SI technique (as described in experimental part). The acquisition begins in c-Si (at the tip of the green arrow in Figure 1.b) and

Figure 1.c)) and ends in the middle of the a-AlO_x layer(at the tip of the red arrow in Figure 1.b) and Figure 1.c)). Figure 1.b) shows a STEM-HAADF image recorded after STEM-EELS SI, the electron beam leaves huge degradation marks which begin in the c-Si and the degradation becomes more important closer to the interface. From a structural point of view, we can observe a loss of crystallinity near the interface in the c-Si: some crystal planes are missing. Furthermore, HAADF contrast over the entire degraded area is much darker than c-Si HAADF contrast, which indicates that in addition to the loss of crystallinity, there is also the formation of chemical compound other than silicon. Thus, to overcome this damage, we decided to decrease the accelerating voltage keeping constant all other parameters (condenser aperture, spot size, exposure time, pixel size) which leads to a decrease in the probe current and therefore in the electronic dose received by the sample. The STEM-HAADF image in Figure 1.c) displays a clear improvement, the crystal structure of silicon is preserved and there is no visible change in contrast. All the EELS experiments which are presented in the rest of this article were carried out with the same dose of $1.03 \times 10^7 \text{ e}/\text{\AA}^2$. The electron dose for our EELS experiments is given by:

$$D_{EELS} = \frac{i \times t}{e \times S}$$

in which e is the electron charge in Coulomb (C), i (C/s) is the current given by the manufacturer as a function of spot size and condenser aperture, t is the exposure time, and S represents the pixel area in $\text{\AA}^2$. Note that the a-SiN_x:H layer and therefore the a-AlO_x/a-SiN_x:H interface already very sensitive to STEM-HAADF imaging, as mentioned above, are all the more sensitive in STEM-EELS. We therefore focused only onto the c-Si/a-AlO_x interface

Figure 2: Comparison of EELS spectrum image recording of two scanning methods at 80 keV. a) and b) are drawing representation of STEM-EELS perpendicular ($\perp$, scan along the y axis) and parallel ($\parallel$, scan along the x axis) scanning over the c-Si/a-AlO_x interface respectively. c) and d) are EELS spectrum corresponding to $\perp$ scan and $\parallel$ scan respectively showing Al-L_{2,3}-edge with their inset showing the entire dispersion of the EELS experiments with AlL_{2,3}-edge and SiL_{2,3}-edge. e) and f) are MLLS profile of STEM-EELS $\perp$ scan and $\parallel$ scan respectively.

Besides the dose control, another acquisition parameter has been studied. We have indeed compared two spectrum image recording techniques on the same sample (same FIB lamella). The first one will be referred as " $\perp$ scan" because the electron beam passes perpendicularly to the c-Si/a-AlO_x interface along the y axis for recording EELS spectrum as depicted by the black arrows in Figure 2.a). The second one, referred as "//scan" because the electron beam approaches, scans and records along a line parallel to the interface along the x axis as illustrated in Figure 2.b). Spectrum c) and d) of Figure 2 and their insets are the result of EELS spectrum image of 1 nm $\times$ 10 nm with a pixel size of 0.2 nm $\times$ 0.2 nm and a pixel time of 0.1 s. For both $\perp$ scan and //scan, spectra were summed along the x axis for data treatment. Spectrum c) and d) display only the beginning of energy-loss near-edge structure (ELNES) of Al L_{2,3}-edge to focus on it while their insets show the full range of our EELS experiments containing the full Al L_{2,3}-edge and the ELNES of the Si L_{2,3}-edge. The edge onset characteristic of Al L_{2,3}-edge of metallic Al is at 73 eV and it arises by a net shouldering, observed in c) and d) spectrum of Figure 2. The c) and d) insets in Figure 2 allow, on the one hand, to identify the shouldering of metallic Al on the whole energy range chosen for our EELS experiments and on the other hand to understand how and where a-AlO_x begins with respect to c-Si in the stacked EELS spectra. Indeed, the shape of Al L_{2,3}-edge is modified for a-AlO_x which is characterized by one peak at 78 eV and another broad peak at 80 eV. For the c-Si, the Si L_{2,3}-edge is located at 99 eV. Thus, the blue spectra corresponds to the c-Si and the red spectra corresponds to a-AlO_x which begins when the 78 eV peak starts to appear. The position and shape of these characteristic edge will be analyzed in more detail in the next paragraph in order to determine the local coordination. On spectra c) and d) from Figure 2, we can observe that the presence of metallic Al varies according to the recording technique used. The metallic Al is located in a-AlO_x and spreads over the c-Si for the $\perp$ scan whereas it is located only in a-AlO_x for the //scan. This shows that the presence of metallic Al might be due to and/or enhanced by an interaction between the electron beam and the structure (more details about this interaction in the Discussion part). Interestingly this interaction can be limited by using the //scan. The semi-quantitative MLLS profiles (explained in the experimental part) e) and f) in Figure 2 allows to show significantly the metallic Al spreading over c-Si and a-AlO_x with better precision than using only EELS spectra. Thus, by using //scan, it reduces the metallic Al spreading in c-Si by a factor of 3.

The following experiments were therefore carried out by //scan.

Figure 3: STEM-EELS experiment recorded at 80 keV. a) EELS spectrum showing Al and Si $L_{2,3}$ -edge of c-Si/a- AlO_x . b) EELS spectrum showing O K-edge of c-Si/a- AlO_x . Those two spectrum allow to highlight that the c-Si/a- AlO_x interface is composed of aluminum silicates (purple spectrum) and Si-O bonds (green spectrum) at the interface. c) MLLS profile and map showing the interfacial layer. d) $T/(Oc+P)$ ratio as a function of the distance to the c-Si/a- AlO_x interface showing high proportion of tetrahedrally coordinated Al in the first layer of aluminum silicate.

After having demonstrated that metallic Al can be enhanced by the electron beam and that therefore it could be an artifact, we can now analyze the c-Si/a- AlO_x interface with more caution. The EELS spectrometer we used has the DualEELS function which allows to acquire two different energy

regions of the EELS signal simultaneously with exactly the same parameters. This is typically what is shown in [Figure 3](#): a) represents the lower energy region with the Al $L_{2,3}$ -edge and the Si $L_{2,3}$ -edge while b) represents the higher energy with O K-edge. Thus, a spectrum in the lower energy region is associated with a spectrum in the higher energy region.

Let us describe the lower part: as already said, characteristic ELNES of a- AlO_x are one peak at 78 eV and another broad peak at 80 eV, indeed for Al_2O_3 compounds this region is related to the studied phase (amorphous, γ , α , β , θ) and should depend on the coordination [21], these two peaks are even often associated respectively with tetrahedral and octahedral coordination [22][23]. However, it has been demonstrated experimentally by NMR [24][25] as well as by simulation [26] that three coordinations can exist in a- AlO_x that are tetrahedral (T), pentahedral (P) and octahedral (Oc) and that their proportion depends on the process conditions and deposition technique used [27]. There are therefore 2 peaks for 3 coordinations. In EELS, the first peak at 78 eV would correspond to the tetrahedral coordination [21] while the second one at 80 eV would rather correspond to a mixture of pentahedral and octahedral coordination. In our case, the peak at 78 eV is the first EELS characteristic that appears. We can therefore say, that tetrahedral coordination predominates in the first layers of a- AlO_x . To show that, we plot the $T/(Oc+P)$ ratio that is very high at the first layer of a- AlO_x ([Figure 3.d](#)). Concerning the ELNES of the Si $L_{2,3}$ -edge, its shape did not change along its thickness, but its intensity gradually decreases to give way to a- AlO_x . There is however an area where the characteristics ELNES of c-Si and a- AlO_x coexist (colored in purple in [Figure 3.a](#))).

The O K-edge in [Figure 3.b](#)) provides more information about this interfacial region. We can observe that O K-edge starts before the Al $L_{2,3}$ -edge of a- AlO_x *i.e.* that there is an area where O K-edge and Si $L_{2,3}$ -edge coexist (green region in [Figure 3.a](#)) and b)). This informs us that there is probably some chemical bond between Si and O. In the purple area of [Figure 3.a](#)) and b), the three edges of Al, Si and O are present simultaneously, which would mean that there is aluminum silicates formation (Al-O-Si bonds) at the interface. And if we combine information from [Figure 3.a](#)) and d) we can see that tetrahedrally coordinated Al are contained in the aluminum silicate region. To highlight and quantify the composition in this region, a MLLS map and profile were done in [Figure 3.c](#)). [Figure 3.c](#)) shows an MLLS profile and map in which we have added an extrapolation of the aluminum silicate to

define the c-Si/a-AlO_x interface. Indeed, as there is an area where a-AlO_x and c-Si coexist (the purple area), we multiplied the c-Si MLLS data by the a-AlO_x MLLS data, these are the purple region on the MLLS map and the purple curve on the MLLS profile. The interfacial region composed mainly of aluminum silicate extends over 2.7 nm which is approximately 2 times larger than the interfacial region measured on the STEM-HAADF image (Figure 1.a)). Indeed, MLLS profile taking into account EELS data, is more precise than the STEM-HAADF contrast intensity in the image.

Discussion

Figure 1 and Figure 2 tend to prove that our sample has undergone several electron radiation damages depending to the scan parameters. Before discussing the composition of the c-Si/a-AlO_x interface, we will try to identify what kind of electron damage takes place in our specimen. It should first be noted that electron radiation damage can be caused either by elastic (electron-nucleus interactions) or inelastic (electron-electron interactions) electron scattering which can be of different types [28][29]. Whether the degradation is due to elastic or inelastic scattering, it can cause microstructure modification of the targeted materials creating rearrangement or breaking unstable bonds.

Elastic electron scattering damages include sputtering and knock-on damages. Sputtering corresponds to surface atom displacement and/or ejection in the TEM column. It depends on the incident energy threshold (E_0 , also called accelerating voltage) which depends also on the analyzed elements. As reported by Egerton *et al.* in [28], light and medium-Z elements like Si, Al, O and N present in the studied samples are removed by sputtering.

Knock-on damages also concern atomic displacement due to E_0 but in the material volume. Each element has a displacement energy threshold E_d in a considered material which can be determined experimentally or by simulations. This energy depends on the structure and so depends on the crystallography, that's why, e.g. for Si, E_d can take different values between 13-37 eV depending on the crystal family plane considered [30][31][32]. Thus, we can determine if the c-Si has suffered from knock-on

damage by calculating the maximum knock-on energy transfer (E_{max}) [20][33]:

$$E_{max} = \frac{4M_e M_a E_0}{(M_e + M_a)^2}$$

, where M_e is the mass of the incident electron and M_a is the mass of the target atom in the material. The corresponding E_{max} in Si for $E_0 = 200$ keV and $E_0 = 80$ keV are respectively 15.6 eV and 6.25 eV. Considering the E_d of Si, knock-on electron damage can occur at $E_0 = 200$ keV. In the literature E_d for O and Al have been determined only for crystalline or polycrystalline Al_2O_3 [3][34][35] and as Cooper *et al.* [36] demonstrated, it is too complex to predict E_d for amorphous materials knowing E_d for crystalline materials because it depends on too many parameters (bond energy, elastic strain energy, average mixing distance...). However, the E_d values of amorphous materials are generally lower than crystalline materials. Taking into account the E_d values of $\alpha\text{-Al}_2\text{O}_3$, Nakamura *et al.* [3] determined that knock-on was ubiquitous for $E_0 \geq 300$ keV, therefore E_0 for a- AlO_x will necessarily be below 300 keV.

To avoid these two kind of electron damages, it is therefore necessary as recommended by Egerton [37] to work below the incident energy threshold E_0 by reducing the acceleration voltage when possible. Thus, concerning knock-on damage, decreasing the accelerating voltage from 200 keV to 80 keV allows to stop knock-on in c-Si and probably in a- AlO_x . However, to stop sputtering damage, an acceleration voltage below 50 keV should be used which is not convenient with most of TEM. Another way to limit sputtering and knock-on damage is to reduce the electron dose which has been achieved as explained before. At this stage, elastic radiation damage does not seem to be the dominant source of degradation.

Radiation damage from inelastic scattering can also be of two types: electron beam heating or ionization damage (known as radiolysis).

Murray *et al.* [2] reported that the crystallization of a- AlO_x into $\gamma\text{-Al}_2\text{O}_3$ was due to thermal process during electron irradiation. It should however be pointed out that a thin film of a- AlO_x started to crystallize at 1073 K [38]. Then, Nakamura *et al.* [3], demonstrated by the calculation and experimentally that crystallization cannot happen only by a thermal process because the elevation of the temperature during TEM analysis did not exceed 6 K. As far as we are concerned, we observed metallic Al mobility after STEM-EELS experiments (Figure 2) instead of crystallization. However, a

sole heat treatment could not induce the transformation of a-AlO_x into metallic Al. Thus, in our case, we consider that heating induced by electron beam can be negligible.

Furthermore, the evolution of the thermodynamically stable α -Al₂O₃ towards metallic Al under electron irradiation was intensively reported [21][39][40][41] and associated with ionization mechanism. Berger *et al.* [42] also characterized metallic thin surface film of Al after STEM hole drilling at 100 keV of Na β -Al₂O₃. Some authors [43][44] have exactly the same EELS characteristic of metallic Al (shouldering of Al L_{2,3}-edge at 73 eV) in a-AlO_x (Al L_{2,3}-edge forming one peak at 78 eV and another broad peak at 80 eV) but the EELS characteristic of Al was expected since they were studying Al/a-AlO_x interface while in our case no metallic Al was expected in the original stack. Indeed, the presence of metallic Al at the c-Si/a-AlO_x interface due to the manufacturing process was not often observed but it has been reported and characterized by NMR for an a-AlO_x deposited by metalorganic chemical vapor deposition (with different precursors than ours) at 480°C [45]. As shown in Figure 2, the shouldering at 73 eV in the EELS SI is characteristic of Al metal and the EELS SI (not shown here) corresponding to the STEM-EELS acquisition at 200 keV of Figure 1.b) showed an enhancement of the metallic Al. So, a decrease of the acceleration voltage (causing a decrease of the electron dose) and a changing in scan direction acquisition from $\perp$ scan to $//$ scan (Figure 2) can modify the metallic Al spreading at the c-Si/a-AlO_x interface. Taking into account those facts, we would suggest two hypothesis:

- i) metallic Al is formed during manufacturing process or by contamination during the process
- ii) metallic Al is due to electron beam irradiation.

Concerning hypothesis i), the presence of metallic Al due to manufacturing process would create positively charged defect sites in a-AlO_x which would lower the field effect passivation. This characterization shows us that the manufacturing process might be modified in order to find a way to remove the metallic Al. We will come back to this point in the last paragraph which deals with the composition of the interface. In the case of hypothesis ii) we believe that the formation of this metallic Al corresponds to a radiolysis process of a-AlO_x. This process has been described by Knotek-Feibelman [46] as an interatomic Auger process which implies a loss of three electrons from Oxygen (O²⁻ to O⁺). Oxygen in the O⁺ configuration is forced to desorb from the surface or to move to an interstitial

position in the lattice. The aluminium ions are left as a metallic plug at the surface in the direction of the electron beam scan. However, it can be seen that only part of the Al-O bonds has undergone the radiolysis process since the fine structures of a-AlO_x and Al coexist on several spectrum. In amorphous matrix, it has been reported that mainly the thermodynamically less stable bonds are likely to be broken or reorganized by electron excitation process like ionization [47]. It is known that a-AlO_x is composed of AlO₄, AlO₅, AlO₆ basic units. The AlO₅ unit is known to be the less stable, it is in particular involved in the crystallization process of a-AlO_x into γ -Al₂O₃ [3]. Therefore, this unstable unit could preferentially undergo the radiolysis process. Assuming the radiolysis is the main process involved in the Al metallic formation, it is known that increasing the acceleration voltage could reduce these damages. [26,35,46]. In our experiments, we have combined several parameters to control this radiolysis process: acceleration voltage, dose, scan orientation. A parallel scan orientation combined with a decrease of the acceleration voltage from 200kV to 80kV, and hence a decrease of the electron dose, could prevent the Al spreading. This seems contradictory with the decrease of radiolysis damages when the acceleration voltage is increased but the influence of the dose seems predominant in our case [28][37][48]. In our experiments, we have chosen to decrease the acceleration voltage in order to decrease the electron dose and also because Hoex *et al.* [23] reported interesting EELS results at the c-Si/a-AlO_x working at 80 keV but it would also be interesting to try other experiments at 200 keV by reducing the dose by modifying e.g. the spot size or the condenser aperture.

Regarding the scan orientation, what could explain the reduction of the radiolysis process from $\perp$ scan to //scan. First of all, once the metallic Al is formed (or is already present at the interface), the driving force which allows its spreading is electrostatic [42]. Thus during the first $\perp$ scan SI, the electron beam has crossed c-Si and a-AlO_x where metallic Al started to spread. At the end of the first $\perp$ scan SI, the electron beam returns in c-Si (to start its second scan) where the metallic Al species created before are attracted and/or dragged by electrostatic driving force spreading metallic Al in c-Si. This mechanism cannot occur by using the //scan since the electron probe stayed in the c-Si during its first scans. In order to stop the radiolysis process, it would be interesting to use a cryo sample-holder which would drastically reduce the electron beam interactions and/or using a TEM equipped with an electron direct detection camera which allows to work with ultra low electron doses.

As explained before, the particularity of a-AlO_x is that it provides both chemical and especially field effect passivation by a large contribution of negative charges near the interface. In the following part, we will discuss how the composition c-Si/a-AlO_x can influence the c-Si passivation. [Figure 3](#) allows to determine that some Si-O bonds are present at the interface for a thickness of approximately 0.5 nm but we cannot give the exact oxidation number of silicon since the shape of the Si L_{2,3}-edge is not modified. Indeed, if the oxidation number of silicon was Si⁴⁺, two peaks at 106 and 108 eV would have been present on the EELS spectra. It is difficult to track down other oxidation signatures of silicon in silicon oxide (a-SiO_x) with EELS, only Batson [\[49\]](#) reported that Si²⁺ gives way to a broad and weak peak at 103 eV. Thus, in the 0.5 nm thick interfacial a-SiO_x, the oxidation number of Si can be Si¹⁺, Si²⁺, Si³⁺. The thin a-SiO_x is therefore oxygen deficient which promotes the presence of oxygen vacancies that would tend to be positively charged [\[50\]\[51\]](#). Nevertheless, those positive charges at the interface could be compensated by the excess of hydrogen intrinsically present in the a-AlO_x or H diffusing from the a-SiN_x:H through the ultrathin a-AlO_x to the c-Si/a-AlO_x interface where it passivates the dangling bonds of the c-Si and could probably form Al-H pairs in a-AlO_x which would enhance the field effect passivation as those pairs have a charge state of -1 [\[26\]](#). Note that hydrogen bonds cannot be characterized with EELS. Whatever the structure or the stoichiometry of a-SiO_x, the basic building block remains tetrahedral[\[52\]\[53\]\[54\]](#). This tetrahedral coordination influences the coordination of a-AlO_x on its first layers which is also tetrahedral [\[21\]\[22\]\[23\]\[55\]](#) as we have been able to characterize at the beginning of the purple region by the predominance of the 78 eV peak in [Figure 3](#). Bonding between (SiO₄)⁴⁻ and (AlO₄)⁵⁻ basic units produces a net negative charge [\[56\]\[57\]](#) thus improving the field effect passivation.

On top of the c-Si surface, there is a mix between a-AlO_x and a-SiO_x that forms an aluminum silicate framework [Figure 3](#). As the passivation stack has undergone several annealings at relatively low temperature, we would rather be in the presence of a non-stoichiometric aluminum silicate (Al-O-Si*) [\[58\]](#). This is coherent with non-stoichiometric a-SiO_x found at the interface. The metallic Al that we found at the interface would be an evidence that the formation of the aluminum silicate occurs through the reaction of Al, O₂ and Si, and therefore that oxidation at the interface is only partial. As we said above, the metallic Al site could contribute to a decrease in the performance of the device by adding

positive charges in the a-AlO_x.

In addition, in this kind of passivation stack, it has been shown by a light induced field effect enhancement study that most of the negative fixed charges are in fact trapped charges and the best candidates for charge trapping in a-AlO_x are reported to be interstitial oxygen sites [59][60]. It is also reported that tetrahedrally coordinated Al specifically contained in amorphous aluminum silicates have a very strong catalytic activity [55][61][62] and could enhance the field effect passivation [60]. This last point is consistent with our results (tetrahedrally coordinated Al in aluminum silicate) and could lead to other investigations.

Finally, one way to improve the performance of the device, would be either to transform the non-stoichiometric a-SiO_x/Al-O-Si* into a stoichiometric and more stable a-SiO₂/Al-O-Si which would bring more Al vacancies (capable of trapping negative charges) and interstitial oxygen negatively charged [58] or to promote the formation of a stoichiometric a-SiO₂ [63][64] to the detriment of the aluminum silicate.

Conclusion

In this work, we begin by studying electron-beam irradiation on the c-Si/a-AlO_x interface. Firstly, we show that decreasing the acceleration voltage from 200 to 80 keV (reducing simultaneously the electron dose from $2.67 \times 10^7 \text{ é/\AA}^2$ to $1.03 \times 10^7 \text{ é/\AA}^2$) during STEM-EELS experiment allows both to preserve the structure at the interface and to reduce Al metallic spreading. Besides, this Al metallic was even more reduced by modifying STEM-EELS scan orientation acquisition from y axis orientation ($\perp$ scan to the interface) to x axis orientation ($\parallel$ scan to the interface). Two hypothesis have been laid out concerning the origin of the metallic Al at the c-Si/a-AlO_x interface. One of the two hypothesis supported the fact that Al is formed by a radiolysis electron-beam process with a-AlO_x. The other one is more in favor of a manufacturing process dependency origin. In both case, our results show that this metallic Al is not stable since it can be spread over the stack by the STEM probe. Otherwise, it could be interesting to establish an experimental plan to test other microscope parameters in order to go further in the study of electron-beam related artifacts.

Regarding the composition of the c-Si/a-AlO_x interface, an ultrathin a-SiO_x layer was found, and above this ultrathin layer, an aluminum silicate layer was characterized. Due to the presence of a-SiO_x and metallic Al site positively charged, the aluminum silicate is probably non-stoichiometric. At this interface, the negative charges improving the field effect passivation would therefore be mostly given by the tetrahedrally coordinated Al which has net negative charges. Finally, to bring more negative fixed charges, the aluminum silicate and/or the silicon oxide at the interface should be stoichiometric, which would bring more interstitial oxygen and Al vacancies known to be negatively charged.

To conclude, this article has shown that the characterization of unstable and non-stoichiometric materials as used in the photovoltaic field is not trivial. These characterizations could be improved using TEM techniques that are applied in biology field such as e.g.: cryo-TEM, cryo-sample-holder or low dose camera [65].
